LIST OF CONTRIBUTORS TO VOLUME LXI

(Exclusive of Anonymous Correspondents)

Those whose names are marked with an asterisk have contributed editorial articles.

ABBOTT, AUSTIN, The Hon.
ADER, HARRIS B., M.D.
ALEXANDER, SAMUEL, M.D.
ALLEN, HARRISON, M.D., Philadelphia.
ALLEN, S. P., M.D., Whitney's Point, N. Y.
AMBLER, C. P., M. D., Canton, Ohio.
ANDERSON, P. L., M. D., Chicago.
ARMSTRONG, HERMAN L., M. D., Radio City, N. Y.
*ARMSTRONG, SAMUEL T., M. D.
ARMSTRONG, W. S., M. D., Atlanta, Ga.
AUDLE, JOHN, M. D., Philadelphia.
ALLEY, PEARCE, M. D.
BALDWIN, EDWIN R., M. D., Saranac Lake, N. Y.
BALL, A. BRAYTON, M. D.
BARBER, CALVIN F., M. D., Brooklyn.
BARLOW, W. JARVIS, M. D.
BARNES, JUSTIN L., M. D.
BARTLETT, E. H., M. D., Brooklyn.
BARUCH, SIMON, M. D.
BECK, CARL, M. D.
BENNETT, M. L., M. D., Watkins, N. Y.
BERYNS, AUGUSTUS C., M. D., St. Louis.
BISHOP, LOUIS FAUGERES, M. D.
BLACK, J. M., M. D., Knoxville, Tenn.
BLACKWELL, ETHEL, M. D.
BLECH, GUSTAVUS, M. D., St. Louis.
BLYER, J., M. D., Des Moines, iowa.
BLODGEIT, ALBERT X., M. D., Boston.
BODENHAMER, WILLIAM, M. D., LL. D., New Rochelle, N. Y.
BONDURANT, E., M. D., Tuscaloosa, Ala.
BOUS, LOUIS, M. D.
BRICKNER, SAMUEL M., M. D.
BROCKWAY, FREDERICK J., M. D.
BROKAW, W. F., M. D., Cleveland, O.
BROWNING, B. RAY, M. D., Littleton, N. C.
BRUSH, ARTHUR CONKLIN, M. D.
BRYANT, JOSEPH D., M. D.
BRYSON, J. P., M. D., St. Louis.
BUCK, ALBERT H., M. D.
BULL, CHARLES STEWART, M. D.
CALLIE, AUGUSTUS M. D.
CALLAN, PETER A., M. D.
CARSON, N. B., M. D., St. Louis.
CATES, BENJAMIN B., M. D., Knoxville, Tenn.
CHAFEE, GEORGE, M. D., Brooklyn.
CHAPPELL, WALTER F., M. D.
CHEESMAN, WILLIAM S., M. D., Auburn, N. Y.
CHUBB, CHARLES H., M. D., Palenville, N. Y.

**LIST OF ILLUSTRATIONS IN VOLUME LXI.**

| The Etiology of Cancer. Facing | 1 |
| The Arthropathies of Locomotor Ataxia. Two Illustrations | 67, 68 |
| Papilloma of the Tonsils. Two Illustrations | 69 |
| A Large Liver | 71 |
| Suture of the Torn Cervix Uteri. Two Illustrations | 72 |
| A New Nasal Speculum | 121 |
| A New Intra-uterine Irrigator, etc. | 121 |
| Non-tuberculous Diseases of Joints. Two Illustrations | 130 |
| Stricture of the Male Urethra. Twelve Illustrations | 135-138 |
| A New Phorometric Table-bracket. | 156 |
| Stricture of the Male Urethra. Diagram | 172 |
| A New Oral Speculum | 189 |
| Sprained Ankle. Four Illustrations | 190, 194 |
| Double Movable Mires for the Ophthalmometer. Four Illustrations | 198, 199 |
| Clitary Wound. | 206 |
| Abnormalities of the Nasal Septum. | 228 |
| Nasal Saws. | 228 |
| Malarial Haematuria. | 229 |
| Operation for Phimosis. | 230 |
| A Frontal Sinus Drill. | 280 |
| Carbuncle-aeid Inhaler. | 294 |
| Brown-Sequard Paralysis. Three Illustrations | 295-297 |
| Clonic Spasm of the Tensor Tympani. Diagram | 327 |
| Bernay's Rosary Bougies. | 354 |
| Tubal Mole Pregnancy. Two Illustrations | 355, 356 |
| Treatment of Pott's Disease. Two Illustrations | 360 |
| Apparatus for Washing out the Stomach | 386 |
| Spinal Supports. Two Illustrations | 388 |
Original Communications.

THE ETIOLOGY OF CANCER,
WITH ESPECIAL REGARD TO
THE PROTOZOA PARASITES OF CANCER.*

By ALLEN J. SMITH, M. D.,
Professor of Pathology in the University of Texas.

Time has not proceeded more than a single generation since the most advanced scientific medical writers were satisfied to regard among that group of formations known as tumors a number of decidedly important neoplasms which have, because of almost positive proof of their parasitic origin, been assigned to a separate position in the classification of pathological products. Even at the present day there are pathologists who continue to classify these two groups, the infectious granuloma and the tumors, as closely related— as they are, at least in many of their peculiarities; yet the appreciation of the etiologic in the one case and the failure of any realization of the causation in the other constitute a decided distinction, reaching into almost every aspect of their nature, relations, and treatment, that the more modern view can scarcely be held precipitate in thus separating processes such as tuberculosis, syphilis, leprosy, and actinomycosis, from the true tumors, enlargements of whose cause no actual knowledge is held. The impulse given to continued research in similar lines by the discovery of the nature of the infectious granuloma was early sufficient to call attention to the analogies presented by the cancerous and sarcomatous groups of tumors to this class of neoplasms; and these have been within the past several years the center of intense attention from microscopists bent upon establishing their parasitic origin and their recognition as members of the same class of new growths. These similarities consist, especially in the histology and clinical course of the growths, the essential features of the histology of the infectious granuloma consist of a central group of epithelial like cells, surrounded by a greater or lesser zone of lymphoid cells, together with a variable connective-tissue stroma. These may vary considerably in the individual examples, and do vary somewhat as to the relations and characteristics of the elements in the different forms of the granuloma. It would require no great imaginative effort to regard the cancerous nodule, with its epithelial cells imbedded in a variable stroma of connective tissue, the whole surrounded by a greater or less amount of embryonal connective-tissue elements in various stages of organization, as conforming to the same type as does the smaller gray tubere. Nor, on the other hand, would it be difficult to regard the sarcoma as the result of a specific cause leading to the production of the lymphoid elements of the same type, the epithelialoid elements being greatly in the minority and perhaps overlooked, or so altered in their characteristics as to be indistinguishable from the embryonal connective-tissue cells which form the tumor. It is certainly suggestive of a difference between tubercle and cancer that the former, typifying the infectious granuloma, should reach a definite stage of degeneration, while no such necessary occurrence can be recognized in the case of the cancers; nevertheless, the well-known fact of the long persistence of the fungus-like variety of tubercle and the rather frequent degenerative accident in case of cancer are conversely suggestive of their similarity. These differences depend, moreover, largely, perhaps, upon anatomical relations with a blood supply which might easily be influenced by generically unimportant differences in structure, such as the amount and kind of stroma in each case. The fact that the epithelialoid cells of cancer seem from histological appearances to be true epithelium, arising and growing from apparently normal epithelium, and that no such connection can be demonstrated in case of the epithelialoid cells of the tubercle, should not seriously mitigate against the possible generic similarity of these formations, judgment being based rather upon the similarity of results than upon the apparent differences of origin. The peculiarities of metastasis, perhaps best seen in the miliary forms of both cancer and tubercle, add a further link to the chain of similarities between these formations.

One need not seek far for further suggestion of an infectious nature in cancer, although it must be confessed that the proof of such infecting power can not by any present means be more than probably predicated. The fact of its especial prevalence in localities of greater or less restriction (Park, Medical and Surgical Reporter, February 18, 1893; Arnaudet, L'Union méd., October 7, 1892; Med.-surg. Bull., June, 1893; Fiesinger, Gaz. méd. de Paris, March 5, 1893; Rev. de méd., January 10, 1893; Williams, Med. Chron., February, 1893; Lancet, September 12, 1891, etc.), scattered here and there over the world, strongly suggests that there are operative causes other than mere structural ones, and that these causes are such as operate the body from without. The corporeal distribution of primary cancers, at orifices and points of constriction of epithelia tubes, the lips, pharynx, pylorus, ilco-caecal valve, anus, cervix uteri, vulva, or base of the bladder, or at parts easily handled, as the mammary or the general surface of the body, may without great effort be interpreted as suggestive of the origin of the growth from abrasions and subsequent inoculation with an infectious agent, although it is quite true that a very different interpretation may be given the same circumstances of position. The hereditary influence which popularly and professionally has been so generally accorded cancerous growths; the instances of apparent infection related by medical writers (Fiesinger, loc. cit.; Arnaudet, loc. cit.; Guelliot, Jour. de méd. et de chirurg. prat., March, 1893); the experiments of Hanau (Wiener medizinische Presse, April 21 to June 9, 1890), Wehr (Annalen of the Univ. Med. Sci., vol. iii., 1890), Moran (Amer. Med.-surg. Bull., June, 1893), von Langenbeck, O. Weber, Lebert, and others, in transplantation of epitheliomatous formations to animals or among animals; of Nayet (La France médicale, June 16, 1893) in inducing epitheliomatous growths in animals by injecting a glycerin extract of epitheliomas of man; and of

* Read before the Pathological Section of the First Pan-American Medical Congress, Washington, September 7, 1893.
Hahn, von Bergmann, and others (La Prat. méd., June 30, 1891; Cornu, La Semaine méd., June 24, 1891; Med. Press and Circular, August 5, 1891) in grafting cancers to different parts of a cancerous patient's body—all stand in closest relation with the belief in the infectious nature of the growth, proof being, however, wanting.

The possibility of a parasitic origin of cancer, as well as of other new growths, was suggested years ago by Paget (Surgical Pathology; Brit. Med. Jour., 1887), who likened the growths produced upon trees by the stings of insects or by the deposition of the ova of insects to these tumors of animal structures.

While there have been at various times (Brault, Arch. gén. de méd., 1885, ii, 586; Rappin, Comptes rend. de la Soc. de biol., 1887; Scheurlen, Dent. med. Worzech., 1887, No. 48; Senger, Deutsch. med. Wochenschr., 1888, No. 14; Baumgarten, Critbl. f. Bakteriol. u. Parasitenk., 1888; Rosenthal, Zeitsch. f. Hygiene, 1888; Kubassoff, Wiener med. Presse, 1890, No. 31, etc.) described vegetable micro organisms as the specific causes of cancer, the failure of confirmation and the discovery in several instances of the same micro-organisms in non cancerous tissues have resulted in the practical abandonment of belief in a bacterial cause, although it is generally accepted that various bacteria may be present as parasitic incidents in cancer.

The apparent protozoan nature of certain bodies in epithelial formations, such as molluscum contagiosum, described originally by Virchow (Virchow's Archiv, Bd. xxii, p. 149), and by a number of investigators since then (Rivolta, Dei parasiti vegetali, Turin, 1878; Bollinger, Virchow's Archiv, Bd. lvii; Neisser, Vierteljahreschrift f. Dermatologie, 1885, xv, 553; and others), and in Paget's disease of the nipple (Hutchinson, Trans. of the Pathol. Soc. of Lond., 1890, 214; Darrier and Wickham, Archives de méd. expér., etc., 1890, i, 1, ii, 47; Ann. de derm. et de syph., 1 and 11; Maladie de Paget, Paris, 1890; Bowly, Brit. Med. Jour., May, 1891, p. 1070; etc.), suggested, moreover, the likelihood of the existence of similar bodies in the allied cancerous formations; although there was no lack of opposition to the belief that the bodies seen in molluscum and subsequently in cancerous tumors were of parasitic nature.

In 1888 Pfeiffer (Zeitsch. f. Hygiene, 1888; Die Protozoen als Krankheitsreger, 1890, zweite Aufl, 1891) called attention to certain bodies he had observed in the cells of the tumor masses of two cases of general carcinosis; these he described as sporozoa, in their development resembling the microsporidia. The following year Malassez and Albarran (Comptes rendus de la Soc. de biol., 1889; Les tumeurs de la vessie, Paris, 1892) announced their discovery of bodies resembling Coecidium oviforme in the cells of an epithelioma of the jaw. Thomas (Fortschr. der Med., June, 1889) described about the same time small cell like structures he had observed in the nuclei of the epithelial cells of glandular cancers of the rectum, breast, and stomach, bodies measuring from four to fifteen micromillimetres in diameter, rounded or oval or somewhat of the shape of pseudonavicella, usually occurring in groups of five or six. The nuclei of the cells in these cases refused to stain well with hematoxylin and eosin, safranin, alun-carmin, and other reagents employed, and were apt to show numerous vacuoles, empty or containing the parasitic bodies or a little granular matter. The following year Sjobring (Fortschr. der Med., 1890, No. 14), who had been studying the processes of nuclear division in a cancer of the breast, noticed certain bodies resembling protozoa, and after careful examination decided such to be their nature. The life history which this author attributes to these bodies is briefly as follows: Small round masses of protoplasm, two micromillimetres in diameter, may be met with free in the tissues or within the cell protoplasm. One of these bodies, for example, penetrates the nucleus of a cell, gradually increases in size, and then passes into the cell protoplasm, where it may remain for a variable time, a slightly granular mass of protoplasm surrounded by a clear zone, but without a cell wall. It may escape entirely from the cell and be found free in the tissue spaces at this period. Eventually, however, it enters an epithelial cell, becomes surrounded by a membrane, and at maturity nearly fills the host cell. Small curved rods, surrounded by bright, hyaline matter and presently becoming encapsulated, develop within the parasitic body—twenty or thirty in number—giving rise to the appearance of a sporocyst. These spore-like bodies after a time escape from the parasite and enter fresh cells to undergo the same cycle. Sjobring was unable to demonstrate a nucleus in these bodies, and for this reason, and from the various appearances presented during the history of the organisms and their evident method of reproduction by sporocyst formation, places them among the sporozoans and probably in the class of the microsporidia. The author states that he found these bodies in six out of seven cases of cancer of the breast which he had examined and in two cancers of other parts of the body.

These descriptions of Thoma and Sjobring found corroborations shortly in publications by Babbiani (Virchow's Archiv, Bd. cxxi, i, 1), Hacke (Comptes rend., de la Soc. de Biol., 1890), Wright (Address at the University of Toronto, 1890), Strobe (Beiträge z. path. Anat. u. allg. Path., 1891, xi, 1), and to a certain extent in papers by Steinhaus (Virchow's Archiv, Bd. cxxvii, i, and Bd. cxxvi, i, 3), Foà (Critbl. f. Bakteriologie u. Parasitenk., Bd. xii, p. 185), Soudakewitch (Ann. de l'Inst. Pasteur, 1892-93), Podwysocki and Sawtschenko (Critbl. f. Bakteriologie u. Parasitenk., Bd. xi, p. 93), Kürstener (Virchow's Archiv, Bd. cxxx, ii, 3), and others. Of the more recent writers Soudakewitch found in the cells and cell nuclei, of glandular cancers especially, small round or oval bodies, sometimes with a membrane about them. By special hardening with osmic acid and subsequent staining in hematoxylin these bodies may be seen surrounded by a clear or granular or rayed zone. If homogeneous, they take the stain but faintly, while the granules or rays surrounding them take a deep hue. Metschnikoff, who had opportunity to examine these preparations, states in a note added to the paper that these bodies are probably coccidia, judging from the appearance of the envelope and its protoplasmic contents. Podwysocki and Sawtschenko fail to note the parasitic bodies within the cell nuclei, but have in the instances studied found numerous examples in the cell body. The second of these
writers, Sawtschenko (loc. cit.; ibid., Bd. xii, No. 1), describes the following appearances which he was able to demonstrate in sections of a cancer of the lip in large numbers: The cell protoplasm of some of the cancer cells presented one or more vacuoles, some of which were empty and which may have been the former resting places of protozoa. In some of these vacuoles were to be seen small rounded bodies, sometimes provided with a deeply staining mass suggesting a nucleus. Often these contained corpuscles (within the vacuoles) had a prolongation, giving rise to a shape like that of a frog’s larva—a frequently noted form. These frog-larva bodies were of varying size, in several instances quite large and long, apparently the wandering stage of the parasite. Thus there might be seen one of these larger, wormlike bodies passing from one epithelial cell to another, or lying between the cells. After thus penetrating an epithelial cell the parasite seems to assume slowly the rounded shape, pushing the nucleus of the cell off to one side, and presently becoming inclosed within a membrane apparently derived from itself. Occasionally several such resting forms may be witnessed lying side by side, surrounded by a separate or by a common capsule. Gradually in this rounded, resting stage the central portion seems to stain more deeply, as if of nuclear nature, and about the margins, especially without the capsule, appear small, round, highly shining corpuscles like spores. Presently within each of these as they increase in size appear deeply staining masses, single or double, rounded, oval, or spindle-shaped. As these sporelike bodies develop about the margin of the parasite the capsule of the latter becomes less clear, apparently giving up its substance to the growth of the spores; and within the body of the parasite there appear a large number of similar protoplasmic masses. The whole mass is now very similar to the sporocyst stage in the development of sporozoos, save that the capsule of the cyst is wanting. What becomes of all these supposed spores is uncertain; some probably pass from the vacolated cell and pursue their life history elsewhere in the body of the infected individual. Some, at least, continue to develop at the site of their formation, swelling out the host cell to its greatest capacity, pushing off the nucleus to one side and often compressing it into an insignificant size. Constantly the marginal spores develop in advance of the central ones. Eventually each of these spores forms from the nuclear-like body in its interior a frog larva-like body, which probably then makes its way into the interior of a fresh cell, assumes the resting form, and goes through a similar cycle. Besides these stages in the life of a seeming sporozoon, Sawtschenko describes what has probably been observed by other writers and interpreted by them as examples of endogenous cell formation—small epithelial-like cells within the host cell, probably the physaliphora of Virchow. The contained cell is somewhat more granular than the protoplasm of the host, and sometimes shows a very delicate meshwork in its substance. It contains a nucleus usually staining deeply, and sometimes a nucleolus. Apparently a further stage of the same kind of body is such a contained cell with two or four crescent-shaped bodies in the interior, strongly suggestive of the pseudo-

...
a young, fully formed parasite." Galloway (Lancet, No. 5, 1893) has recently affirmed his belief before the Royal College of Surgeons in the protozoan nature of the various bodies described on account of their apparently organized structure, their distinctive staining reactions, and their analogy to well known protozoa. Kürsteiner (Virchow's Archiv, Bd. cxxxii, H. 3) has announced that he has found bodies corresponding to the descriptions of the above named writers in a papilloma of the bladder and in papillary adenomata of the uterus.

Not all of the investigations into the question of the existence of animal parasites in cancer, however, have been productive of favorable comments from their authors. There are those who have denied totally the parasitic character of the appearances described by the authors quoted, and who would explain the phenomena mentioned entirely upon the ground of cellular degenerative changes or of changes induced by faulty or special methods of technique. There are, too, those who, while acknowledging the similarity of the bodies to sporozoan, deny that sufficient evidence has been adduced to warrant a belief in their parasitic nature. Thus, van Heukelom (Uebrfl. f. pathol. Anatomic, 1890, p. 704), from a study of over two hundred tumors, while able to find the bodies in question, was of the opinion that their smaller forms might easily be explained by the idea of cell degeneration—perhaps leucocytes with fragmentation of their nuclei. The larger bodies might perhaps be epithelial cells of peculiar shape, although he did not believe them to be necessarily degenerated cells. Borrell (Arch. de méd. expér., et d'anatom. pathol., ii, p. 786, 1889), preceding the latter writer, also mentions the two groups, the small intracellular bodies and the large forms of the supposed parasites. The former, the younger, the eozidian forms of those favoring the idea of parasitism, he would regard as examples of endogenous cell formation; and the second, the forms corresponding to the sporocyst stage of the parasites, he believes to be derived from the tissue elements of the cancer by some peculiar cellular degeneration. So, too, Firket (Uebrfl. f. allgemein. Pathol. u. pathol. Anatomic, 1890, No. 20) objects to the belief in the protozoan nature of these bodies because he has seen similar appearances in the epithelium of the skin covering a fibroma where no evidences of cancer were present. He believes that from pressure by the tumor these bodies had been produced through degenerative changes. The idea of cellular degeneration as explanatory of these various appearances is also sustained by Schütz (Mikroskopische Carcinombeobachtungen, Frankfurt, 1890; Münch. med. Wochenschr., 1890, No. 33), Török and Tommasoli (Monatsh. f. Dermatologie, 1890, No. 4), Klebs (Deutsch. med. Wochenschr., 1890, Nos. 24, 25, 32), Delépine (British Medical Journal, September 9, 1892), Duplay and Caxin (Seventh Congress of Hygiene and Demography; C. xin, Arch. gén. de méd., January, 1892; Duplay, Gaz. des hôpitaux, 1883, p. 210), Ribbert (Deutsch. med. Wochenschr., 1891, p. 1179), and recently by Gibbes (Amur. Jour. of the Med. Sc., July, 1893). The last named investigator has contributed a valuable addition to the literature antagonistic to the parasitic theory of cancer origin. Believing it impossible to prove the various so-called parasitic bodies to be distinct elements of protozoan nature at the present time by any but staining methods, he sought to find some differentiating reagent capable of distinguishing the supposed parasites from the tissue cells of the animal body. Employing the well known Coeacidum unforme from the liver of a diseased rabbit as the control, he produced a test stain* giving the parasites the desired difference of hue from that given the epithelial cells of the organ when the tissue had been hardened by the ordinary alcohol method. In sections of various cancerous growths hardened in the same manner and stained by this method, Gibbes was unable to demonstrate the parasites, although after hardening the same tissues in bichloride-of-mercury solution, Müller's fluid, and in several other solutions, the appearances of protozoan bodies were easily appreciable. He concludes from this that the supposed protozoa of cancer are no more than the results of faulty methods of hardening. Further study and confirmation of these results of Gibbes are exceedingly desirable at this stage of our knowledge, although it is of course possible that even the failure to take a stain, except under conditions of previous hardening by special reagents, may be due to peculiarities inherent to the supposed micro-organisms. Cornil (Jour. de l'anatom. et de la physiol., 1891, No. 1), Hansemann (Virchow's Archiv, Bd. cxxxii, H. 3), and others hold forth the possibility of mistaking various stages of cellular division for these supposed sporozoa. Strobe (Ziegler's Beiträge, 1891, xi, H. 1) and Steinhaus (Uebrfl. f. allgemein. Pathol., 1891, No. 2) admit that some of the bodies to be found in the cancer cells are extremely suggestive of protozoa, and are inclined to believe that in some cases at least they are real protozoa; but do not accept for that reason the belief that they are an ontological factor of the tumors. Steinhaus, in a second paper (Virchow's Archiv, Bd. cxxvii, H. 1), distinctly denies the protozoan nature of the bodies described in the center of the "pearls" of squamous epitheloma, attributing them to cellular changes; and in the same journal Virchow adds a note reiterating his original views of the endogenous formation of these bodies and their want of ontological significance.

Besides the supposed animal parasites which have attracted attention, Russell has recently (Brit. Med. Jour., December 13, 1890) described as the real cause of cancer a body which he believes to belong to the fungi. This body, because of its affinity for acid fuchsin, he speaks of as "the fuchsin body," and states that it may be found with but few exceptions in cancer and in no other structures. These fuchsin bodies occur in groups of two, three, four, or more, generally have a clear space about them, and are bounded by a capsule, are spherical in shape, measure from four to twelve micromillimetres in diameter, and are

* The stain is thus made: Dissolve 2 c. c. of aniline oil in 10 c. c. of rectified spirit; add enough distilled water to make 150 c. c.; filter; add 2 grammes of cyanamine sulphate. Label No. 1. Stain No. 2 is a one per cent. solution of iodine green. Leave sections in stain No. 1 for ten minutes; wash them in water, then in alcohol; place them next in stain No. 2 until a dull purple color is assumed. Wash thoroughly in water, dehydrate in alcohol, clear in clove., mount in xylol balsam.
homogeneous and structureless in appearance. Russell states that they appear to grow by germination and are found in the rapidly growing parts of the tumor. Numerous writers, however, have shown that these bodies are by no means characteristic of cancer, and less attention is at present paid the claims of the last named investigator than those of the writers above mentioned (Ballance and Shattock, Brit. Med. Jour., March, 1891; Dean, Lancet, April 6, 1891; Duplay and Casin, loc. cit.: Rennie, Austral. Med., Gaz., March, April, May, 1893; etc.).

Attracted by the evident sincerity of the writers describing the various suspected parasites in cancerous tissues, as well as influenced by a long-existing faith in the eventual discovery of some such parasitic cause for carcinomatous and sarcomatous tumors, the writer was led to carry on a series of examinations in the same line, with the purpose of confirming or denying the views already advanced. From the results of these observations it is not possible to definitely assert or deny the correctness of the views of the older observers, however, and they may only be offered as additions to a growing study. The general impression, however, gained from these examinations is not unfavorable to the belief in the presence of protozoa in cancers, and has only added to the confidence of the writer in the ultimate success of those seeking to demonstrate the general features of the protozoan theory of cancer causation.

It is scarcely likely that all the appearances described as parasites will bear the test of continued observation, and it is just as improbable that the full list of these organisms has thus far been announced. From the writer's experience he is led to regard the most of the minute, intracellular bodies, the rhizapid-like inclusions in the pearls of squamous epithelioma, the ameboid bodies of Korotneff, as well as the fuchsin bodies of Russell, as being of cellular origin, degenerative in nature. The larger, intracellular and extracellular bodies, the various appearances of spongiosiform formations, the peculiar double contoured coccidiform bodies, the gregarine-like bodies, the bodies containing faeciform and p-endotheliales-like corpuscles, and the bodies in the so called phyaliphora—these seem scarcely to be denied from our present knowledge, yet the proof of their veritable protozoan nature is not possessed.

The various forms of these parasites encountered by the writer bear the greatest similarity to the bodies described by Podwyssozki, Sawtschenko, and Korotneff, and it seems probable that the last-named observer is correct in his statement that if they be protozoa these bodies should be classed (at least some of them) among the gregarinidae. It seems quite likely, however, that there exist several varieties, some of which are coccidias, and others perhaps rhizopods. Thus the specimen presented in Fig. 8 can scarcely be otherwise interpreted than as a rhizapid in the process of germination, and it is possible that some of the ameboid bodies of Korotneff may belong to the same group (if they really exist as parasites). To the more important question as to their nature, Are they really independent organisms, or are they parasitic bodies? there is but one argument to be offered in answer—the analogies they present to known stages of the life history of recognized species of protozoa. On the other hand, there are grave reasons for doubt—the evident mistakes of a number of writers in relation to some of the forms described, the failure of such stains as that of Gibbes to differentiate these bodies from the cells of the structure in ordinarily prepared tissues, and the long list of acknowledged possibilities of mistake. Nevertheless the similarities to known protozoa are sufficiently strong to make one disposed to accept some of these corpuscles as independent beings, possibly the emasculating factor of the tumor in which they occur.

Twelve growths were examined, all hardened by the ordinary alcohol methods or entirely in absolute alcohol. Of these, three were epitheliomata of the lip, two of the penis, one of an inguinal gland secondary to an epithelioma of the vulva, one a fungating epithelioma of the breast, two glandular cancers of the breast, one a cancer of the uterus, one a cancer of the testicle, and one a cancer of the prostate. These tumors were stained either with hematoxylin, hematoxylin and eosin, borax-carmine, alum carmine, or safranin. Of these the specimens stained with hematoxylin and those with safranin presented the most easily recognized and most numerous examples of the supposed parasitic bodies. It may have been from faults of preparation, especially of hardening and fixation, that these bodies in the specimens examined were less numerous than one would imagine from perusal of the writings of the continental investigators. Foà, it is true, has called attention to the fact that one should not expect to find swarms of protozoa in every portion of a specimen, and states distinctly that he succeeded only in a limited number of specimens and only in isolated portions of the preparations. The writer has repeated this experience. Although in most specimens there are numbers of appearances which future study may perhaps show to be parasites, yet fairly suggestive and convincing examples are by no means found in great numbers and often require prolonged search in well-studied preparations.

Of these twelve specimens, in three—a cancer of the breast, a cancer of the prostate, and an epithelioma of the penis—the sought for bodies were not found; and of the remainder, the individual specimens varied considerably in their relative frequency of exhibition of the so called parasites. The most commonly observed variety of these phenomena was that of a single intracellular, round or oval mass, sometimes distinctly contained in a space (Fig. 7), again completely filling (Fig. 10) the vacuole in which it occurred. Such a mass usually measured from eight to fifteen, twenty or more micromillimetres in diameter, was more or less granular, and sometimes contained (Fig. 10) a large number of deeply staining, round, oval, or faeciform "clumps." At times the greater portion of the epithelial cell was occupied by such a body, which generally was stained slightly more or less deeply than the protoplasm of the cell. These differences in the intensity of coloration probably depend in a measure upon the age of the parasite, the older specimens taking the stain less readily than the more actively developing bodies. The protoplasm of such a body is generally somewhat more granular and refractive than that of the host cell. Occasionally, instead of these
in intracellular bodies being single, there may be found a large group in one cell. Similar bodies are to be found between the cells of the tumor in the lymph spaces, and occasionally in the structures away from the epithelial portions of the cancer. The large numbers of hollow cells (Fig. 4), with their nuclei flattened and pushed to one side by pressure, so as to create the "seal-ring" appearance, are often doubtless to be regarded as the former resting places of these intracellular bodies, the granular detritus often to be seen in these vacuoles being probably the remains of degenerated parasites. In but one or two instances (Fig. 7) were the cell-like bodies, interpreted as examples of endogenous cell formation by certain writers, encountered. From our present views of cellular origin it seems unlikely that such an interpretation can be entertained, and from negative evidence at least one can assert their probable parasitic nature. Sawtschenko in his description of the sporocysts to be seen in cancerous formations states that these arise from the intracellular bodies, in which he recognizes the frequent presence of a nuclear body. This was not, however, observed in the cases examined by the writer. The intracellular bodies, save those last described, were non-nucleated; and in no instance was there a cyst formation observed within the cellular limits (unless the occasional occurrence of a group of intracellular bodies as above described be regarded as examples of sporocyst formation). Excellent examples of sporocysts (Fig. 9) were found a number of times, in all of which there could be easily shown a distinct membranouslike wall to the cyst. The sporelike bodies within these cysts were very like the intracellular bodies in structure and in coloration, but differed in the individual cysts as to whether there could be found the small, deeply staining interior masses. These deeply staining contents, usually few in number, from their frequent arrangement in pairs are suggestive of active reproduction by fission and are probably the germinal portions of the containing body (Fig. 17). In none of the specimens examined, probably on account of the intensity of the staining, could a structure be recognized in these contained masses, which look much like drops of some hyaline, deeply stained substance. The claim that these clumps are masses of chromatin is not to be gainsaid, but the fact that they have a decidedly deeper hue than the small chromatin masses in the epithelial nuclei somewhat sustains the belief that they are not of cellular origin. Within the sporocysts the spore bodies are found, ten, twenty, thirty, forty, or more in a mass, like minute hyalidids (Fig. 9). They are faintly granular, quite variable in size, round, flattened, and spindlelike in shape, the differences probably depending upon circumstances of pressure within the cyst. The wall about these bodies is distinct and clearly cut on the inner surface, and is apparently reinforced on the outside by adjacent flattened cells of the tumor, and by an occasional bit of connective tissue. It will be recalled that in the descriptions of Podwyssozki and Sawtschenko the intracellular sporocysts showed the spore formation as an exogenous production at first, the spores developing in size so that the larger were constantly seen on the borders of the mass, the capsule of which early disappeared from view. It is possible that the writer has failed to recognize these cyst formations until they had developed to such a stage that the epithelial host cell had been entirely absorbed along with the original cyst membrane; yet in that event it seems quite as singular that the very clear cyst wall observable in some of the specimens examined should have been undescribed by these authors. Rather would it appear that two distinct appearances have been noticed, and further study will be required to indicate their relation.

Besides the intracellular bodies and the sporocysts, the gregarinellike body (Figs. 1, 3, 4, and 11) was one of the most readily recognizable appearances when present. It was observed in three of the specimens examined—an epithelioma of the lip stained with safranin, an epithelioma of the penis stained with borax-carmine, and a fungating epithelioma of the breast stained with hematoxylin. This body, not recognized by any of the writers quoted save Sawtschenko and Korotneff, is spoken of by the latter as the "rohalocephala" of cancer, from the thickened anterior extremity. This form of the supposed parasite is an elongated, wormlike body, varying in the instances studied from about twenty micromillimetres to double that length. The anterior end is rounded, not as thickened as Korotneff describes in his specimens, and usually contains a small amount of granular matter and a few masses of a deeply staining substance. The individuals observed in the epithelioma of the penis had a head not unlike that of a minute tapeworm, the opposite end terminating in a rather blunt point (Fig. 1). The interior of these bodies was structureless, granular anteriorly, hyaline about the borders and toward the posterior extremity. No nucleus was observed in any of these. It might doubtless be objected that these gregarinellike forms are but peculiarly shaped epithelial cells, devoid of a nucleus, and perhaps slightly altered in their constitution, this alteration having caused them to take on the staining reagent in the slightly different degree observed. This may be true; but the frequent occurrence of the described shapes and the occurrence of such an apparent conjugation as shown in Fig. 4 lead one to considerable confidence in their parasitic nature. So, too, one can not definitely say that the appearances presented by the sporocysts and their contents are not due to some cellular change, a number of cells in one locality undergoing contemporaneous alteration to the production of a material similar to hyaline substance; yet in this case it is scarcely likely that the contents of the spore bodies should be so arranged as to suggest multiplication rather than fragmentation, or that such falseform and spindle shaped masses (suggestive of the pseudonavicella stage in the development of the gregarines) should be assumed by degenerating elements. The same argument must be presented in case of the ordinary intracellular body. In but a single instance has the writer been satisfied to accept any of the bodies observed as showing the double contour of the true coccidia; and never has there appeared to him any suggestion of the segmentation as described so clearly by Korotneff, Foa, and others. The failure of these forms, however, as well as of the in-
SMITH: THE ETIOLOGY OF CANCER.

Jan. 5, 1895.]

TRANNUCLEAR BODIES, MAY DEPEND ON DIFFERENCES IN THE TECHNIQUE OF PREPARATION. IT IS NOT NECESSARY, HOWEVER, TO ACCEPT THESE TO FILL OUT THE PROBABLE LIFE-HISTORY OF THIS SUPPOSED PARASITE, WHICH THE AUTHOR IS DISPOSED TO CALL AMONG THE GREGARINES. IF THIS CONJECTURE BE CORRECT, IT IS INTERESTING TO NOTE THAT THE GREGARINE OF CANCER IS THE FIRST GREGARINE PARASITE OF MAN, IF NOT OF THE VERTEBRATES GENERALLY. FREQUENTLY FOUND IN THE INVERTEBRATES, THE GREGARINES HAVE IN VERTEBRATE PARASITISM GIVEN PLACE TO THE ECCIDIA AND PERHAPS THE MICRO- AND MYXO-SPORIDIA.

THE WRITER IS NOT DISPOSED TO ACCEPT KOROTNEFF'S AMOEBOID STAGE, WHICH IS LOGICALLY CORRECT, IT IS TRUE, BUT WHICH, IF THE SIMILAR APPEARANCES SEEN IN THE SPECIMENS EXAMINED BY THE WRITER (FIG. 15) ARE IDENTICAL, ARE ALMOST SURELY THE RESULT OF PROTOPHASMIC CHANGE AND CONTRACTION. SO, TOO, THE SMALL, TRANNUCLEAR BODIES SHOULD NOT BE UNHESITATINGLY ACCEPTED. THEY MAY BE OF PROTOZOA, YET THE VERY GREAT POSSIBILITY OF MISTAKING INERTIC FIGURES OR MASSES OF ALTERED CHROMATIN, AND THE ABSENCE OF NECESSITY FOR THEIR PRESENCE IN THE LIFE SCHEME OF THE PARASITE, HAVE SEEMED TO BE SUITABLE REASON FOR THEIR REJECTION FOR THE PRESENT.

WHATEVER ELSE HAS BEEN SAID, HOWEVER, IN RELATION TO THE SUBJECT, THESE TWO FACTS STAND OUT IN BOLD RELIEF, AND THESE MAY BE OFFERED AS THE WRITER'S CONCLUSIONS: (1) CANCER PRESENTS A COARSE AND CLINICAL ASPECT ANALOGOUS TO THOSE OF FORMATIONS OF PARASITIC ORIGIN. (2) WITHIN AMOEBOID TISSUES OCCUR BODIES WHICH CLOSELY RESemble THE DIFFERENT LIFE STAGES OF PROTOZOA, OR SPOROSYPH¥M, OR GREGARINE.

EXPLANATION OF PLATE.

FIG. 1. A, GREGARINE FORM OF PARASITE; B, EPITHELIAL CELL; C, GREGARINE FORM WITH APPARENT FLAGELLUM. FROM EPITHELIOID OF PENIS, STAINED WITH BORAX-CARMINE. HALF-INCH HOM, OIL-IMMERSION LENS, O. 4, ZEISS.

fig. 17. ruptured spore-like, showing escape of spore bodies which are apparently older than in fig. 9, as shown by their hинтер ions and by their containing numerous pseudonavicularia-like bodies.

the differential diagnosis of traumatic intracranial lesions.

by charles phelps, m.d.

subject: to bellevue and st. vincent's hospitals; conducting surgeon to governors hospital.

(continued from vol. 6, page 815.)

the extent to which traumatic lesions aid in the determination of centers of functional control.—the present study of intracranial lesions has been, up to this point, independent of their relation to special areas of functional activity. the question consecutively arises as to the possibility of connecting symptoms with the seat of injury in accordance with known laws of cerebral localization. the difficulties in obtaining clinical confirmation of the inferences derived from physiological experiment, which have been recognized in the examination of idiopathic disease, are exaggerated in cases of the complicated lesions of traumatic origin. the number of cases in the series which i have collected is sufficiently large to have a certain value, either positive or negative, in determining how far such a relation exists. it is conceded that a motor zone, contiguous to the Rolandic fissure in the human brain and analogous to a similar area experimentally demonstrated by comparative physiologists, has been heretofore abundantly verified by observation of both idiopathic and traumatic lesions. this is also sufficiently illustrated in the cases which i have described, though in a relatively small proportion of their whole number, since violence, even when inflicted upon the vertex, is so generally transmitted to the base, where its limited destructive effect is exerted, that the motor region is likely to escape from injury. the general and local paralyses which follow the functional or structural impairment of the motor centers are so well understood that further reference to them as they have occurred in my own cases may be properly omitted.

a much larger proportion of the cases which i have instanced relate to injuries sustained by regions of the brain in which function has been less successfully studied in the light of clinical observation. these have presented symptoms which are to a certain extent diagnostic, and at the same time incidentally confirmatory of views of cerebral localization founded upon physiological induction.

no part of the brain has been so frequently involved in fatal injury as the frontal lobes. they have been lacerated in more than one third of all the cases which i have subjected to necropsy examination. it is evident that unconsciousness or delirium attends any form of lesion situated in any region of the brain; but mental disorder or decadence, apart from these, has been supposed to be dependent upon a definite and limited structural alteration, and assumed to be of the prefrontal convolutions. the influence of direct frontal injury in so many cases upon the integrity of thought or its manifestations can hardly fail to be of assistance in determining the accuracy of this localization.

the series of one hundred and thirty necropsies includes forty-nine instances of laceration of one or both frontal lobes. in twenty-three cases morbid mental conditions had been inappreciable through unconsciousness, which was both primary and permanent. in the remaining twenty-six mental changes were observed in nineteen. an examination of the seven cases of frontal laceration which were without mental derangement shows that one, in which early symptoms were not obtainable, involved both lobes; the other seven were confined to the right side; so that, in practically every instance, every one with a history in which the left lobe was lacerated, there were evidences of mental default or abrasion. the special manifestations of disordered intellect which they presented have been outlined in individual histories and scarcely require repetition in detail. loss of memory, especially of the fact, manner, or circumstances of injury, confusion of ideas, inability of comprehension, incapacity of mental concentration, indifference, fixed or transitory delusions, apathy, melancholy, or stupor, were of constant occurrence, singly or in combination with each other. a condition of mental confusion and incoherence with delusions, which occurs at a late period, is often confounded with the early delirium of cortical irritation. the lacerations were not always of the same character, situation, or extent. five had led to almost complete subcortical disintegration, eight of the cortical injuries were confined to the base, and the others, wholly or in part, were upon the antero-superior surface. in one instance the interior of both lobes was practically destroyed. the symptoms held some relation to the nature and extent of the lesion; in the subcortical excavations there was in each instance abrogation of mental power, rather than an aberration in its manifestations. the patient's condition was noted at the time in the several cases as "sluggish," "apathetic," "without sign of intelligence," or as "apparently devoid of power of comprehension." it was generally characterized by torpidity and indifference. in the cortical injuries, in place of comparative default of intelligence, there was incoherence, overpermed memory with delusions, or the stupor which comes from confusion of ideas and mental indifference; the mind was alert to external impressions, though they were not always rightly comprehended. it is a noticeable fact that in a large proportion of cases the superficial injuries were upon the inferior surface, which has been classed as a latent area. the distinctions which i have made in the mental condition, as it follows cortical or ex-
tensive subcortical laceration, are broadly drawn, but I believe will be found to be justified in an examination of the cases which I have cited.

The converse proposition that frontal laceration alone, of all traumatic conditions, occasions a direct loss or derangement of intellectual function, independent of delirium or unconsciousness, is only a little less absolutely true. In the same series of one hundred and thirty necropsies death had been preceded by such deficiency or derangement in four instances in which this injury was not disclosed. In one of these, a case of gunshot wound of a parietal lobe, some slowness of comprehension was the only mental symptom aside from a hysterical melancholia which had led to a suicidal attempt; this may be properly excluded, as mental disease existed before the reception of injury. In each of the other three mental disorder and subsequent decadence were well pronounced. In one, general hyperemia and edema were excessive, with a small hemmorhage into the substance of an optic thalamus; in another, simple general confusion with edema only existed; and in the third, a large localized subarachnoid serous effusion compressed the frontal lobes. The exceptional cases, but three in number, in which these lobes, though not lacerated, were still the part solely affected by a limited lesion in one and included in the general lesion in the other two, can not be said to controvert the presumptive evidence derived from physiological observation and so generally supported by the results of pathological investigation that the control of the intellectual faculties is located in this region of the brain.

The difference in the morbid mental conditions which have followed laceration, as it has affected the left frontal lobe or the right, I believe has not been suggested by physiological experiment or noted in previous observations of traumatic lesions. In every case of the present series in which consciousness was retained or regained, and in which the history was known, laceration of the left frontal lobe has been attended by intellectual aberration apart from simple delirium; in similar cases in which the right lobe has been lacerated without destructive injury of the left, there have been in their larger proportion no symptoms of mental disorder, and in the remainder there has been only stupor or active delirium, as may happen in diffused lesions and in other parts of the brain.

The examination of lacerations which involve the temporoparietal lobes has had scarcely more than a negative importance. They are forty-five in number and were attended by an aphasic condition in but a single instance. In the greater number of cases in which laceration existed twenty-eight, entire unconsciousness, the grave of so many possible symptoms, precluded its recognition. In the seventeen cases remaining it was confined to the base, a supposed latent area in eight, was unplaced in one, was an extensive subcortical excavation in three, and in four was situated in the lateral region, which includes the centers of speech. The instance of aphasia is detailed in the historical abstracts, and the essential lesion, which was purely lacerative, extended quite through the cortex of the first and second left temporal convolutions. The arachnoid was unruptured, and there was no cortical or other local hemorhage; Broca's convolution was unaffected. In the other cases of laterial laceration there was slight injury of the first or second convolution. None of the forty five cases, save the one mentioned, presented any symptom, unless it were a convulsion, which could be considered indicative of temporoparietal injury. In the sixty-two tract lacerations which comprise all those in which the frontal and temporal lobes were implicated, separately or together, there was but the one instance of aphasia mentioned. In the recovering cases it will be found to have been of more frequent occurrence.

It has been assumed that hémorrhage compressing the centers of speech is a cause of aphasia. I am compelled to dissent from this proposition, not only as contrary to the results of my own observation, but from general anatomiical and pathological considerations. The compression, if exerted by a small amount of blood, must be direct and accurately applied; if it be by a hemorrhage large enough to include these small spaces in the wide expanse of cerebral surface through which we are brought in touch with the world without, the individual defect is lost in the general obscuration of all the faculties which attends the grosser injury. A pial hemorrhage from meningeal concussion in this region is likely to be scant and diffused; a cortical hemorrhage, if small and confined to either area in which the control of speech resides, is derived from laceration of the part itself to which as the primary and more potent lesion the result must be attributed; an epidural hemorrhage while yet in moderate amount acts indirectly and inadequately upon the temporal or lower frontal region through the dura which acts as an efficient shield. In wounds of the middle meningeal artery, in which the effusion of blood may in time become excessive, the loss of consciousness which then ensues abrogates speech with all the other manifestations of intellectual life, and there no longer remains a question of aphasia.

I have never met with a pial or cortical hemorrhage of local origin which suggested an interference with the integrity of speech, nor one where consciousness had been retained or restored in which blood had descended from the vertex in amount sufficient to produce this result by compression of the frontal or temporal lobe. My experience has assured me that such an event, if it happens at all, is much too unusual to justify the statement made that it is a contingency to be expected. I have seen cases of large epidural hemorrhage in which consciousness was gradually lost before death or relief by operation, but I have never recognized aphasic symptoms at any time during their progress.

There is a case of motor aphasia attributed to hemorrhage reported by Dr. M. A. Starr in which the patient was trephined with great benefit. The amount of blood was small and limited to the motor region. He immediately regained some power of speech, and a little later indicated some mental improvement. I have already expressed a belief that intellectual and emotional impairment is not occasioned by traumatic hemorrhage. There were evidences of both in this case which the amount of blood dis-
covered and removed was certainly insufficient to explain. It is necessary to assume laceration in order to account for their existence, and it seems more than probable that the same lesion occasioned the aphasia; it might readily have escaped notice in the comparatively small opening of operation, more especially if it were entirely subcortical within the visual area. The patient, I am told, after a lapse of years is still aphasic, a fact difficult to understand if dependent upon so small a hemorrhage as described.

It by no means follows that hemorrhage was the cause of symptoms because immediate improvement followed operation. The removal of a small portion of bone not infrequently relieves morbid cerebral conditions though the lesion remains undiscovered and unknown. Examples of successful results from operative failure in cranial surgery are as varied as the conditions which demand interference; there is one such in the present series of cases* in which traumatic convulsions of several days' continuance were immediately and permanently controlled by trephining both in the region of direct injury and at the supposed point of contre-coup, though nothing abnormal was discovered and nothing more was done.

I am unable to accept this case of aphasia as a result of hemorrhage even as an exceptional phenomenon.

There are a number of instances of laceration of the cerebellum, but they can be hardly said to have afforded distinctive symptoms. It was in each complicated by other lesions, and the indications were those of laceration and hemorrhage in general, and it might be with added localizing signals of injury to areas of which the function has been more accurately defined. If the cerebellum has any concern in the maintenance of bodily equilibrium, it is not likely to be disclosed in traumatic cases.

The pons was occasionally contused; it was hyperemic, edematous, or in some part studded with hemorrhagic extravasations, varying from the size of a robin's shot to an effusion a half by a quarter of an inch in its diameters; but resultant symptoms, if they existed, were merged in the general traumatism.

In some cases of injury of the medulla there were respiratory changes of importance, perhaps it might be better said, of interest, since they preceded death by so short an interval that there was no longer question of prognosis or of treatment. The constant lesion was some form of hemorrhage causing direct compression. An extension of a hyperemia from the pons, or even of a slight edema, seemed to be void of effect. The symptoms were those of pulmonary edema, cyanosis, or a marked reduction in the frequency of the respiration. The first and second might be considered characteristic after exclusion of other causes of apnea; the infrequency of respiration when progressive and extreme is almost if not quite pathognomonic. In three instances in which the respiratory acts were reduced to no more than two in the minute, radial pulsation was continued for two and three minutes after respiration had entirely ceased, as sometimes happens after mechanical occlusion of the larynx or trachea.

The more inaccessible regions of the brain are not exempt from destructive alteration. I have described cases in which the corpus striatum, the optic thalamus, the corpus callosum, the gyrus fornix, or a portion of the fornix was contused or lacerated, and this was sometimes the only localized injury in the midst of general contusion. There is the same insuperable difficulty in connecting symptoms with lesions of the optic thalamus or corpora striata as existed in case of the cerebellum. They are not sensitive to minor injuries, and in the severer lacerations, which I have seen extend even to practical disintegration, the patient may lie motionless and unconscious with no apparent symptoms which are not afterward explained by discovered lesions of the adjacent motor or sensory areas.

I have unsuccessfully endeavored to verify the existence of heat centers in the human brain by an examination of temperatures following intracranial traumatism, though such centers seem to have been experimentally demonstrated in the lower animals. The multiplicity of lesions, their wide extent and indefinite outline, render the results of accidental injury necessarily uncertain in comparison with the accurately limited cerebral wounds which are inflicted in vivisection. In some instances very high temperatures have attended laceration of regions which correspond to the heat centers determined by experimentation. I have at times thought that this was especially true of injuries of the frontal lobe immediately anterior to the corpus striatum, but these were always included in more extended cortical ruptures or subcortical excavation, and I have observed that large lacerations elsewhere, even in parts unsuspected of special influence upon the control or production of heat, may be accompanied by temperatures equally exaggerated. The only limited injury of the corpus striatum attended by any considerable rise in temperature was small, and was complicated by a frontal laceration quite sufficient in itself to account for the thermic condition. In another case in which there was a large extravasation into the corpus striatum, three eighths by a quarter inch in its diameters, temperature did not exceed 101°. In still another case the right corpus striatum was completely disintegrated and the left corpus striatum and the right optic thalamus lacerated, yet the temperature rose only to 102.2° in the eight hours and a half which preceded death. In an instance of extravasation into an optic thalamus with excessive general hyperemia and edema, in which the clot was as large as a cherry pit, though the final temperature was 105.4°, there was no elevation above 100° till the fifteenth day. Lacerations of the fornix and corpus callosum were followed by much higher temperatures. Laceration of the pons in one case developed an excessively high temperature, but in others there was no unusual elevation. Cortical centers, as they have been described, are topographically too indefinite to afford data for accurate comparison of cases. I believe, however, that the highest temperatures which I have recorded have not corresponded to injuries of tissue in what I understand to be their situation. Lacerations of any part of the cortex have been attended by marked elevations of temperature, quite as great when...
at the base as when in the uncertain neighborhood of the
"cruciate centers."

The opinion which I have formed from an analysis of
my first series of cases that high elevations of temperature
from traumatic laceration of the brain were dependent
upon general nutritive changes rather than upon lesion of
limited thermogenic or thermotic centers has not been
disproved or modified by subsequent experience. It is im-
possible to predict the result of further clinical observation,
but Dr. C. L. Dana's examination of intracranial hemor-
rhages of idiopathic origin, in which he reaches the same
conclusion, tends to confirm my belief in the correctness of
my original impression.

I have been equally unable to connect the occurrence
of certain circulatory phenomena with lesion of definitely
limited vaso-motor centers of control. The lack of sym-
metry in the characters of arterial pulsation upon opposite
sides of the body, which has been frequent, and the dark
flash upon the face which I have noted in two cases of
very different import, are to me as yet astrologically and
pathologically inexplicable.

The results of a general analysis of all the cases which
I have recorded up to the present time, so far as they re-
late to functional localization, may be summarized in the
following propositions:

1. That the control of the intellectual faculties resides
in the frontal lobes, perhaps exclusively in the left, and
that manifestations of their aberration or default are due to
a destructive alteration which is almost invariably
laceration.

2. That the control of the faculty of speech, resident in
the frontal and temporal lobes, is impaired by structural
alteration alone.

3. That characteristic disturbances of respiration are
caused only by compression of the medulla from hemor-
rhage.

4. That high elevations of temperature, while depend-
ent in occasional instances upon diffused contusion of the
brain substance, are ordinarily the result of limited lesions
which are confined to no special regions or centers of control.

(4) Pyogenic Parenchymatous Inflammation.—There
remains a parenchymatous inflammation of pyogenic char-
acter. It is an infrequent result of traumatism and is
of limited form except when produced by the intrusion of a
foreign body, as of a bullet or drainage tube. I
exclude cases of infection from direct laceration which
sometimes follow neglected compound fracture with
wound of the dura. They are surgically unpardonable, and
at the present time ordinarily due to the stupidity of the
laity rather than to the carelessness of the surgeon.
They afford no question of diagnosis, since the pyogenic
process alike involves the brain, the membranes, and the
surface of the wound, and is open to visual inspection.
The few cases which have been admitted to my service
were recognized without difficulty.

The infrequency of central or true abscess as a result of
traumatism is confirmed by my experience, in which it
has occurred but once in a series of three hundred cases—
once in the fronto-parietal and once in the parieto-occipi-
tal region beneath the angular gyrus; in both it succeeded
a compound depressed fracture of the vertex without
wound of the dura, and was situated at an appreciable dis-
tance from the point of cranial injury. In the first case,
after elevation of the bone and some primary rise in tem-
perature, there were no general symptoms till the twenti-
eighth day, when a few drops of pus escaped from the wound
and a cavity was discovered two inches and more away
from the opening in the skull. At this time there was a
little mental dullness and slight facial paralysis with a
scarcely noticeable elevation of temperature; recovery
soon followed. In the second case the wound healed, and
there were few indications of trouble beyond those depend-
ent upon some enlargement of the cervical glands till the
twenty-second day, when the patient somewhat suddenly
began to suffer from acute frontal headache, became del-
irious, somnolent, hemiplegic, and within twenty-four
hours hemianesthetic, with unconscious and involuntary
evacuations, and with infrequent pulse and absolutely nor-
mal temperature. The abscess, which was small, was dis-
covered and drained, but death ensued sixteen hours after
operation. Both cases conform to the dictum of von
Bergmann that no traumatic abscess occurs without wound of
the integument, and are not inconsistent with the bac-
teriological opinion that parenchymatous inflammation of
the brain is always septic. Von Bergmann, however, is in
error in his general proposition. In a circumstantial re-
port of the second of the cases mentioned, I referred to a
specimen in the collection of Dr. H. M. Biggs which in
connection with its history affords conclusive evidence
that an "open wound in the head or soft walls of the cra-
nium" is not essential to the formation of a traumatic ab-
seoss. In this case a youth of seventeen was struck in the
forehead by a baseball and suffered temporary unconscious-
ness; there was neither cranial fracture nor wound of the
scalp, and in two or three days he had apparently recov-
ered, though headache persisted. Later there was impair-
ment of vision and eventually total blindness. His death
occurred suddenly about six months after the reception of
the injury. The abscess occupied the whole left frontal
lobe, encroaching upon the parietal, displaced the tentorium
backward, and compressed the right hemisphere. It is unnec-
sessary to multiply instances, as a single one is suffi-
cient to show that a possible general rule is not to be re-
garded as absolute. The distinction is important in diag-
nosis, for in a large class of cases it prevents the exclusion
of a condition which always must be reckoned with as a
possibility at least. I have no doubt that the external
cephalic wound usually exists, and that as the shortest
route by which the pyogenic germ can travel it is the one
by which entrance to the brain is likely to be expected.

In the report to which I have referred I attributed the
location of the abscess to a limited subcortical contusion
and, as I think, demonstrated the correctness of my con-
clusion. Von Bergmann again errs in making a statement
too positive when he denies the existence of this lesion
except as a product of extreme violence, which "shatters
the entire skull." Bruises and lacerated wounds of the
brain are demonstrably very much more frequently super-

It seems proper at the conclusion of a summary of cases in which the value of symptoms has been established by necropsy to refer to those which by reason of recovery have been heretofore disregarded as improbable of affording positive evidence of the pathologic condition upon which they depended. I believe no differences in symptomatology will be found to exist except in degree, and in many instances the early progress of the case is not at all indicative of the final result. There is probably no symptom which occurs in fatal cases which may not be noted in those destined to a more favorable termination, except the infrequency of respiration which follows compression of the medulla; and no other symptom which is less characteristic, present, except elevation of temperature. Even in temperature the distinction is not absolute; it does not apply in cases of hemorrhage, and only to the later stage of meningial inflammations and of the morbid conditions occasioned by lesions of the parenchyma. Not only in the beginning but for a considerable time afterward temperature may rise absolutely higher in a recovering case than at any time in the course of one which is to end in death; but in general it is less pronounced. I have never known it to exceed 101°, and rarely to attain so great an elevation.

The symptoms altogether exhibit no greater differences, as the issue varies, than obtain in other types of disease.

In illustration of the cases in which the significance of symptoms has not been demonstrated by the direct inspection of pathologic lesions I have abstracted the histories of a certain number, of which some ended in recovery and others in death, but without necropsy. This class includes one hundred and four as yet unpublished cases, in addition to the sixty six which appeared in my first series. Many of these are fractures of the base or vertex, or uncomplicated general contusions in which symptomatology, diagnosis, and results were so simple that they have scarcely more than a statistical value. I have selected from the remainder some which have special interest on account of symptoms which made diagnosis clear, or which occurred in such combination as to make their interpretation difficult.

Case I.—Male, aged thirty-five years, fell while dancing and struck the back of his head on the ballroom floor; no loss of consciousness, and no other indication of injury till thirty minutes afterward, when the right upper eyelid began to droop.

On examination five hours later, symptoms were confined to right eye and appendages; complete ptosis, external strabismus, pare-is of all the ocular muscles, imperfect accommodation, and diplopia; normal pupil and retina. At the end of eighteen months there was still some weakness of the ocular muscles, but no ptosis. The right pupil was permanently dilated.

Case II.—Male, aged twenty-eight years, received a contusion of the right parietal region, and on the second day began to exhibit symptoms which were observed at the time of examination ten days later: wide dilatation of left pupil; incomplete paralysis of all the ocular muscles and of the elevator of the upper lid of the left eye; anesthesia of the left conjunctiva and of the mucous membrane of the left nostril, with loss of smell on that side, and intense and constant pain in all the
parts included in the distribution of the fifth cranial nerve on the left side. No paralysis of the facial muscles. Some numbness of the left upper extremity. No other symptoms. Ophthalmic examination by Dr. Callan disclosed some cloudiness of the fundus and enlargement of its veins in both eyes; accommodation very imperfect. Two weeks after the injury the hearing in the left ear was lost. The patient is still under observation.

Case III.—Male, aged forty years, fell from a truck and struck upon his head; partial loss of consciousness; profuse hæmorrhage from right ear; wide dilatation of left pupil; temperature, 99°; pulse, 92, and respiration, 23. Second day: slight delirium; mental stupor; no response to questions; temperature, 100°. Third day: severe general convulsion, beginning in left arm and hand; both pupils afterward widely dilated; temperature, 100° to 106°. Fourth day: similar convulsion, but less severe; temperature, 99° to 100°. Eighth day: mind clear, but torpid; no recollection of an accident having occurred; speech slow and somewhat aphasic; headache and continued dilatation of pupils. Twelfth day: mental condition normal; temperature, 99°+. Discharged without further symptoms on the twenty-ninth day.

Case IV.—Male, aged sixty-five years, fell thirty feet; consciousness lost, and regained twenty hours after admission to the Presbyterian Hospital; left hemiplegia; temperature, 98°, which fell in four hours to 97°; pulse, 70 to 80; normal pupils; lacerated wound of scalp. Transferred to Bellevue Hospital eighty-two hours after reception of the injury. There was then delirium with delusions; restlessness; no recognition of changed surroundings; normal pupils and respiration; no paralysis; temperature was 100°-5°; pulse, 112. For ten days continued restlessness and at times delirium, with lack of urinary control; temperature, 102°-6°; pulse and respiration moderately accelerated. After that time mental condition became normal, at first only during the day, and all symptoms disappeared. Seventeen months afterward his mental and physical condition was entirely restored.

Case V.—Male, aged fifty-five years, fell unconscious in the street. On admission, profound shock and entire unconsciousness; wound of scalp in right posterior parietal region; free hæmorrhage from right ear and uniform contraction of pupils. One hour later, rigidity of left arm and, to a less extent, of left leg. Consciousness restored in twenty-four hours, and a little later the pupils became normal and the mind clear. Temperature on admission, 98°, declined to 97-4°, and rose in twenty-four hours to 99-4°; pulse and respiration normal. On the third day, temperature, 99-6°, and only psychic symptoms; mental processes a little less slow than on the previous day, but memory defective. No recollection of anything which happened after leaving home in the early morning, some hours previous to the accident; memory of words and facts equally deficient. Upon questioning, the patient said that he lived at "No. 4 in the Ninth Ward"; then remembered that it was opposite a school, which he called "skull," and finally that it was in Grove Street. On the following day he had again forgotten the name of the street, and its mention awakened no remembrance; he mis- placed many words, and could not be brought to recognize his errors. A week later he had much general headache, realized that his mind had been greatly confused, and was still ignorant of all that had happened since leaving his house. He was discharged on the eighteenth day, his temperature and mental condition having been normal for several days.

Case VI.—Male, aged forty-five years, thrown from a truck in collision; admitted in shock and still unconscious; pupils contracted; temperature, 97-5°; pulse, 52; respiration, 18; twelve hours later, temperature, 97-5°; pulse, 50; respiration, 12; in fourteen hours, consciousness restored; temperature, 98°. Second day, no recollection of injury, previous occupation, or married condition. Third day, cæchymosis over right mastoid process and extending upon the back of the ear, not previously apparent. Fourth day, the patient, after much questioning and trouble, was enabled to remember his residence and occupation; temperature, 102°. During the rest of the week his temperature declined and mental condition improved, though he was still irrational and at night required mechanical restraint. In the second week he was rational at times; he was capable of expressing the generalization that a man's mind is clearer by day than at night, and described correctly the manner in which he received his hurt, though he again forgot the circumstances and denied that he had said anything about it; he was irritable and forgetful, even of the outrage to which he considered himself subjected in the taking of his temperatures; he had delusions, saw imaginary persons, and heard unreal voices, made contradictory statements about the injury which he had suffered, and was much annoyed at the attempts which were made to get from him some coherent and consistent history. Early in the third week his temperature became normal, his memory and other mental faculties were restored, and he was discharged from the hospital.

Case VII.—Male, aged forty-five years, mind impaired by alcohol; severe head injury, loss of consciousness, hæmatoma in left temporal region, profuse hæmorrhage from left ear, and slight epistaxis. Temperature, 98°; pulse 90; respiration, 24. Second day, a little delirium, rigidity of both arms, and left facial paralysis; both upper and lower; temperature, 100-2°; pulse, 100; respiration, 24. Incision made through hæmatoma revealed linear fracture of left zygomatic portion extending into the base. In the three days following, the temperature and mental condition became normal and facial paralysis nearly disappeared. Two days later temperature rose to 100-5°, facial paralysis increased, left side of face and neck became swollen, and delirium supervened. From this time there were recurrent maniacal attacks, lasting less than twenty-four hours, in one of which he was transferred to Bellevue Hospital and soon afterward escaped. He was at a subsequent period sent to an asylum for the insane, and is now, after sixteen months, at home, but of recognized unsound mind.

Case VIII.—Male, aged thirty-eight years, fell from a second story window; unconscious and delirious on immediate admission, and in same condition when transferred from alcoholic ward to surgical service next day. Compound depressed fracture of left temporal bone, extending into the occiput between the curved lines; irregular dilatation of the pupils; internal strabismus of left eye which was afterward found to be congenital; pulse slow and full; breathing stertorous; no control of urine and faeces. The bone was elevated, and an epidural clot, which extended only toward the base, was removed as far as practicable; no discoverable dural or subdural lesion. Third day, left radial pulse fuller and stronger than the right; partial left lower facial paralysis and dysphagia. Fourth day, violent delirium. Fifth day, dysphagia and cessation of bilateral variation in radial pulse; delirium continued, with a short interval in which it intermittted. The symptoms were variable until the end of the fourth week; delirium of different grades at different times alternated with periods of quietude and rational intelligence; various delusions were more or less persistent; dysphagia, lack of urinary and faecal control, and facial paralysis still continued. After this time mental improvement was progressive, and in the seventh week the mind was entirely clear. At the end of eight weeks recovery was complete, and twenty pounds lost in weight had been regained. The temperature on admission was 97-5°, on the second day 102°, and after operation 101-4°; it subsequently declined to normal at the end of
the second week, and after ward varied from normal to 99°+. The
pulse and respiration were varied, but never frequent. At
the end of fifteen months he suffers no mental impairment.

Case IX.—Male, aged thirty-one years; fell two stories
upon an iron beam; unconscious and delirious on immediate
admission; wound above the left eye and contusion of the left
shoulder; loss of urinary and fecal control, which was not re-
gained. Subsequently the patient was usually delirious at
night and stupid during the day, and without other general
symptoms; he was only once or twice able to make coherent
reply to a question asked. He died in profound coma at the
end of twelve days. Temperature on admission was 99°, rose
gradually to 105° on the ninth day, and was 104°½ just before
death. The pulse was 82 on admission and the respiration 24,
and both afterward varied each day from moderate to extreme
frequency.

(To be continued.)

A CASE OF
Pemphigus Chronicus Hæmorrhagicus.

By R. S. DUBS, M.D.,
CHICAGO.

On the 25th of October, 1894, I was called to Deerfield, a
suburb of Chicago, to see a patient who had been sick for some
weeks and whose ailment (as I was told) was an enigma to the
physicians who had attended him. The patient, Mr. D. F., an
intelligent, strongly built farmer seventy-three years of age, I
found to be suffering from pemphigus.

History.—The patient assured me that nothing of the kind
had ever been known in the family. His father died at sixty-
two years of age of pneumonia, his mother at seventy-three
years of a “stroke of paralysis.” Of his six brothers and sisters
all grew up to maturity. One brother died in his thirty-third
year of “lockjaw,” one sister in her forty-third year of a
“throat trouble” which had been of long standing. The four
others are still living and enjoying good health, the eldest being
seventy-seven years of age. As to himself, the patient says he
had measles when a child, at eighteen and thirty years of age a
swelling of the glands of the left armpit. This was of short
duration only, exceedingly painful, and passed away the first
time upon the application of leeches, the second time under the
application of poultices, neither time breaking open. In his
thirty-third year he had an attack of “bilious fever.” Since
then, for forty years, he has been neither sick. All of the patient's
children, live in number, have grown to maturity and are strong,
healthy men and women. In his family there has as yet been
no death; all his grandchildren are living too. The patient's
wife tells me that all her children were, in their first year,
troubled with “eczema capitis,” which in each case lasted several
months. One of the sons, thirty three years of age, is
troubled with a local eczema—viz., “salt rhonx”—and has been
from youth up.

From this history we can find no aetiological moment for the
patient's pemphigus. He is a member of a healthy family, as
far as can be discovered, wholly free from every so-called
constitutional disease, for which the health of his own children and
grandchildren give ample evidence. As to the “eczema” of
his children, if it must have an hereditary aetiology, it might be
found on the maternal side of the family. The acute swelling of
the lymphatic glands of the axilla and his “bilious fever”
surely can form no basis for assuming the existence of any con-
stitutional disease.

The patient describes his present disease as follows: About
the middle of last June (1894) he experienced a burning sensa-
tion about the navel, where, upon looking, he found a number of
blisters of about the size of a white bean. In a few days he
found scabs and pus there (pus coeli having most probably been
introduced by scratching with the finger-nails). About a week
later he noticed the same burning sensation on the back between
the shoulder blades. His wife says that it looked just as if he
had been scalded there, there being several blisters upon a red-
dened skin, and that a yellowish fluid escaped when she opened
them. In July the chest was similarly affected, the symptoms
always being the same—viz., a burning sensation apparently
caused by blisters of from the size of a white bean to that of a
twenty-five-cent piece, which burning pain was invariably al-
leviated by opening the blisters and applying a salve. In August
the limbs were affected, the region of the large distal joints, the
wrist and ankle, being first attacked, and from here gradually
spreading over the whole limb; and when the thighs and arms
(in contrast to the forearms) had been attacked, the disease
spread rapidly upon the trunk. At the end of August the whole
body, the scalp, the beard, and parts of the face, and the mucous
membrane of the mouth had been attacked, the only exempted
parts being the ears, the face between the eyebrows and the
mustache, the vola manus, the planta pedis, and the penis. The
patient explicitly remarks that it was not until August, when
the limbs had become affected, that the disease manifested the
tendency to spread in continuation of the blisters already formed
—i.e., when a blister had been opened the skin immediately
bounding it was, as he says, “lifted off,” so that it practically
amounted to the blisters “growing larger and larger.” As to
their treatment, the patient pointed to a bureau top covered with
bottles and several jars of salve, and remarked that within the
last few weeks he had been troubled with salivation (due to
mercury or to the presence of the bullae in the mouth?).

Status present.—The patient is a man of middle height, has
a strong frame, well-developed muscules, and a moderate amount
of adipose tissue. For seventy-three years of age he is very well
kept. The face is pale, has a careworn expression, and shows
signs of emaciation. The pulse is quite arrhythmic, about eighty
a minute, hard—arterio-sclerosis, but no calcification—of mod-
erate height. There is no fever temperature. Upon examining
the organs of the chest I find the lower boundary of the lung in
the right mamillary line in the seventh intercostal space at the
top margin of the eighth rib. All over the chest, upon auscul-
tating, rhonchi sono et stibilantes—volumen pulmonum actu-
unt. The valvular tones of the heart are clean, the second pulmonary
tone is sharply accented. The rhythm of the heart-beats is very
irregular. The urine is of a light yellow color, not exceeding
1,200 to 1,400 c. c. a day, has a specific gravity of 1'027 to
1'029, is clear and of a weak acid reaction. A small amount of
albumin is present; tests, boiling and addition of acetic acid and
potassium ferrocyanide + acetic acid; no sugar; urobilin and bile
pigment tests negative. There is a satisfactory motion of the
bowels daily and the patient's appetite is good. As to
the nervous system, the right pupil is permanently larger than
the left, but both react promptly upon light and accommodation.
The knee reflexes are present and slightly increased in
intensity. The sensibility of the skin shows no changes from
the normal. The appearance of the patient when stripped of
his salved clothes was pitiable indeed. The color of the skin
varied from a pale yellow to a bright, glossy red, very many
parts being of a dull bluish, almost leaden color. The cubital
regions—r. g., covering the lower third of the arm and the
upper third of the forearm—presented a bluish, livid color, the
skin being rough, dry, covered with fine scales, some scabs, and
bulla varying in size from that of a white bean to that of a silver
dollar, which were fied, half filled only, and wrinkled. The
outskirts of this discolored region of the elbows were not sharply delineated, but passed more or less imperceptibly into the reddish, slightly inflamed-appearing skin surrounding it. Upon the thorax there were blotches of the size of a dollar bill wholly devoid of epidermis, many large flaccid bullae, and some round ones of the size of a nickel five-cent piece, almost hemispherical in shape, well filled, giving signs of considerable tension; besides these eruptions and denuded parts very many seabs, some superficial, reminding one of impetigo, some high in the center, with the edges turned up, often showing several layers, and of a dark, red-brown color, reminding one of ripa. The legs presented an appearance similar to that of the arms, discolored about the knees; from here, extending up and down, scattered vesicule and bullae of the two kinds above mentioned, and seabs. The patient held the arms flexed in the elbow, and the legs bent somewhat in the knee. The parts affected were the scalp, forehead, bearded parts of the face, mucous membranes of the mouth and palate, neck, trunk, and limbs, the only parts wholly exempt being the soles of the feet, the penis, the palms of the hands, the face between the eyebrows and the mustache, and the ears. The parts most affected were the lyoid region of the neck, the chest over the sternum, the umbilical region, the skin over the oval tendons of the caulis, the lower parts of the thorax over the angles of the ribs, the nates, the regions of the trochanter, the flexor side of the thighs over the projecting hamstring tendons, the knees, the extensor side of the ankle joints, the elbows, and the flexor side of the wrists. The patient says that while he was still up the scotel regions caused him great discomfort. More or less common to all these affected parts is a decided discoloring of the skin between the seabs and bullae, mostly of a dull, livid character. Wherever this coloration is present, the patient says there have been “a number of successive crops of blisters.” Besides these parts affected, which were more or less continually exposed to mechanical irritation, there was an unmistakable symmetry to be noticed in some cases—e.g., large bullae just in the middle of the extensor surface of the thighs, a symmetrical distribution of the eruptions upon the forearm (extensor side) and upon the chest and abdomen. I could not but be impressed by this apparent symmetry, where mechanical irritation could hardly be accepted as the immediate cause. The eruptions were of two kinds. They arose in a very short time, often within the space of an hour. Those of one kind were flaccid, irregular in shape, the uplifted epidermis wrinkling somewhat as though only in part distended with fluid, and varying in size from that of a white bean to that of a dollar bill. Even if they were small, by gentle pressure their size could readily be increased, the contents, as it were, burrowing farther under the epidermis. Their color was dependent upon the color of the skin upon which they stood, varying from a pale yellow and a bluish, leaden tinge to a bright red. The bullae themselves were well nigh translucent, except where a greater amount of blood was to be found in them. The contents were fluid, but clotted if caught up. Under the microscope would be found red blood corpuscles, sometimes more, sometimes fewer, many white corpuscles, and frequently shapeless masses of detritus. After removing the raised epidermis the rete Malpighii, presented a very different appearance, and to me it seemed clear that the appearance of the intact bullae was largely dependent upon the condition of this stratum. Where the skin had an apparently normal color the Malpighian layer was a uniform red, not glossy (showing little moisture), and very little blood oozed through. Here, if properly treated, the surface would soon regain its normal appearance. Where that bluish, leaden color prevailed, this discoloration would be found after removing the epidermis, but here the process of healing was slow, a suppurating surface invariably presenting itself. Where the skin had a bright red color, was hot to the touch, and tight (apparently put on the stretch), here, after removing the epidermis, would appear a red, glossy, blood-bespotted surface; and in these cases a scab was quickly formed.

Now, apart from these flaccid, irregularly shaped bullae there was a second kind. These were almost round, well filled almost hemispherical in shape, never larger than a twenty-five-cent piece, averaging the size of a nickel five-cent piece, and were of about the consistence of a lipoma. Upon opening them little or no fluid escaped, the contents being a jellylike mass. It was necessary to cut them off the skin, so this mass adhered to the Malpighian layer. The contents invariably presented a dark-brown color. By applying pressure their size would not increase. The microscope showed the presence, in this jellylike mass, of a network of fibrin (it dissolved readily in dilute acetic acid) in whose meshes were very many red blood-corpuscles, these exceeding by far the number of white corpuscles, many with more than one nucleus. The white blood-corpuscles varied greatly in size, some being in a state of disintegration. There were also reddish masses of detritus here and there. I should like to call attention to the fact that while the covering epidermis was still intact, before any lesion of the same could be detected, the contents of these bullae would present this semi-solid consistence and hemorrhagic appearance; and that the scab, which I shall now describe, would be formed without the bulla having been opened or its having burst open (this latter never happened with them to my knowledge). The seabs which would form, if they were left to themselves, would be dark brown, high in the center, tapering toward the periphery, which in time turned up; and then a continual exudation from under the scab took place, its center being tightly adherent nevertheless. In time they would present the appearance of layers, much reminding one of ripa. If these bullae were at once cut off or removed with the scissors, the scab formed would not differ at all from those formed upon the sites of the flaccid bullae, and would present all the characteristics of an impetigo. Upon the thorax, abdomen, and back, between the bullae and seabs (often the surface upon which they stood) the skin at places had a bright-red color and glossy appearance, and was infiltrated, hard, and hot, and such places were bounded by a distinctly visible (because of its red color) and palpable wall. This zigzag wall bounded such a surface, extending, with very irregular projections, over the umbilical, hypochondriac, and mesogastric regions of the abdomen and chest, and over the back about from the inferior angles of the scapula to the iliac crest on one side, on the other extending over the nates to the thigh. Within the boundaries of this wall the parts not affected by eruptions showed a fine-scaled desquamation (as though strewn with small scales) much reminding one of pityriasis, with all the other characteristics, however, of erysipelas. In one case the wall extended directly across a large space denuded of epidermis, dividing it into two parts. There was no fever, and I could not conclude that the patient suffered more buring here than elsewhere. If it was erysipelas, it surely was of much later date than the pemphigus. I may remark that during the first week of treatment it wholly disappeared.

Therapy.—Internally I gave 4 1/2 grains of quinine hydrochloride three times a day during the first week, later twice a day only; and arsenious acid in compressed tablets once a day after dinner, beginning with 0046 of a grain and quite rapidly increasing to 015 of a grain a day, which dose I continued some weeks.

Externally I applied warm baths (of 95° F.), with an addition of bichloride of mercury, at first an ounce to the bath,
A CASE OF EPIDEMIC CEREBRO-SPINAL MENINGITIS, CURED.

By W. Jarvis Barlow, M. D.,
House Physician, Mount Sinai Hospital, New York.

J. B., aged fourteen years, newsboy, was admitted to Mount Sinai Hospital on July 10, 1894, in the service of Dr. Manges, with whose kind permission the case is reported.

Family history negative. Parents could remember no previous sickness; always a strong and healthy child. The day before admission the boy was suddenly attacked with headache, vomiting, and prostration. No history of traumaism. He vomited often during the day, and had much pain in the head, abdomen, and limbs. In the evening he became slightly delirious, and the parents noticed a slight rigidity of the head.

On admission the patient was unconscious; temperature, 102° F.; pulse, 110; respiration, 26; face flushed; eyes brilliant and fixed; head rigid and slightly retracted; tenderness and stiffness of muscles of neck.

Examination of heart and lungs negative; abdomen tender, but no retraction; liver and spleen negative; papellar reflexes increased; movement of all extremities good. Soon restlessness and delirium became more marked, and with difficulty could only temporarily be controlled. The following day the symptoms were all severer. Increased retraction of head and stiffness of neck; no movement now being possible; marked tenderness over occiput and along the whole cervical region of the spine. Papils react well; no strabismus or nystagmus. Abdomen extremely tender, with well-marked taches cérébrales. Papillary reflexes and all the skin reflexes increased. No ankle clonus.

First Week.—The fever followed an irregular course; lowest temperature, 100° F.; highest, 104°. Pulse at first rapid, then slow. Photophobia and intense hyperesthesia; alternating delirium and stupor; no nystagmus; irregular movements of extremities.

Second Week.—Temperature still irregular; normal at times. Pulse, 70, small and compressible. Reflexes of limbs varied much; increased at times, then diminished, in one or both legs. Alternating delirium and stupor still marked. Papils dilated, reacting well; fundus of eye normal. Herpes labialis well marked. Beginning emaciation. Stiffness and flexion of forearms and hands.

At the end of this week (July 23d) both lower extremities were rigid and in a state of flexion, more marked on the right side.

Urine always contained some albumin; casts, hyaline and granular, now appeared.

Third Week.—Temperature higher, 102° to 104°. Extreme rigidity and retraction of the head. Flexion and stiffness of all the extremities. Marked emaciation. Photophobia and hyperesthesia less marked. Delirium giving place to stupor and coma. For two or three days had difficulty in deglutition. Retention of urine and feces.

Fourth Week.—Temperature lower, 99° to 102°. Pulse higher, 110 to 120. Involuntary urination; hyperesthesia still marked; reflexes varying the same. Tongue dry, brown, and fissured. Coma deeper.

Fifth Week.—Temperature subnormal; pulse small and weak; emaciation extreme; coma still marked. Papils react well; no nystagmus; fundus of eye normal.

Sixth Week.—The patient began to show improvement; less stiffness of head and extremities; all can be moved without pain. Temperature normal, and on August 14th the patient showed consciousness. Voluntary urination and defecation. All symptoms abated, and on August 16th consciousness was complete. Contractures of extremities disappeared gradually. Appetite returned.

Seventh Week.—The urine contained considerable quantities of pus; held in reaction. The temperature rose for a few days—remitting type—and the boy suffered much from pain on the left side of the abdomen. There was distinct resistance and tenderness over the region of the left kidney. Under treatment, however, all symptoms subsided, and in several more days pus disappeared from the urine. After this convalescence was uninterrupted.

Ninth Week.—The patient out of bed, and on September 9th was able to walk. All special senses normal. Tongue clean; no tremor. Intelligence complete. September 20th, discharged from hospital cured.

The treatment of the case consisted in the first two weeks...
of ergot in large doses, bicloride of mercury, indoform, bromides, and stimulants. Morphia and hyoscine to control delirium. For the temperature spiking the body freely, and in the second week a few plunge baths at a temperature of 65°, which subsequently were abandoned on account of the pain and discomfort. Later, tonic treatment and forced feeding.

A recovery so complete without impairment of intelligence or any of the special senses, after so protracted a course, with well marked symptoms, it seems to me, makes the case worthy of publication. The time was there any eruption, although not correctly looked for. The interesting fact of the pyelitis on the left side seems difficult of explanation, and no mention of such is made by authorities to which I have had access.

FREE BLOODLETTING IN PUERPERAL ECLAMPSIA.

By D. DWYER, M. D.,
FROST CEM, PA.

On Friday, November 2d, about 9 p. m., I was called to see Mrs. J. M., who was, as she supposed, about to be confined. On my arrival at the house, I found her in bed, apparently quite comfortable. The first thing which I did, of course, was to make an examination. From this I concluded the labor had not as begun, and, by the way, previous to my arrival, she had had no pains other than some stomach irritation. I could find no dilatation of the os, and was about to leave and return to my office after having remained about an hour, when she suddenly complained of dizziness of vision and in a few moments complete blindness. I anticipated the future, as we all, as practitioners of medicine, know what this means.

It was only a very few moments until she went into a convulsion which, indeed, was very severe. I could do nothing, only keep the teeth apart at the next. However, I had my chloroform ready and administered it in the usual way, and I am sorry to say with little effect. I remained at her bedside till five the next morning, when I left and returned to my office to see if I could find anything in my library that would enlighten me on the subject, and there, as Professor Ford, of the University of Michigan, used to say, “I succeeded in failure.”

It was utterly impossible to get any medicine into the stomach, as she was unconscious from the first convulsion until we resorted to bloodletting. The convulsions came on every fifteen to twenty minutes. On the next morning, about eight o’clock, I called Dr. Blackshear in consultation, and on making an examination we found the os considerably dilated.

What then were we to do? We tried injections, but they were of no avail. We then, as the heading of my article indicates, resorted to free bloodletting. We opened the median basilic vein and drew therefrom a quart and half a pint of blood. We had no sooner done this than the patient regained consciousness and was immediately delivered of the child, which, in our opinion, was at about the seventh and a half or eighth month; it lived for four to five hours. The woman got along very well with medication. As soon as she would take any, we gave diuretics and cathartics.

This I consider a rare case on account of the extreme amount of albumin in the urine.

Now, I hope that none, and especially the younger practitioners of medicine, will hesitate to bleed, and bleed freely, in puerperal convulsions.
CORPORAL PUNISHMENT FOR CERTAIN FORMS OF CRIME.

A meeting is to be held at the Academy of Medicine on Wednesday evening, the 9th inst., under the auspices of the Section in Hygiene, to discuss the propriety of petitioning the Legislature, through the State Medical Society, to enact a law by which corporal punishment shall be inflicted upon certain criminals, especially upon those who beat and otherwise maltreat women. No class of people in the community is more familiar with the results of such criminal practice than physicians, for they are summoned to attend to the injuries which have been inflicted. Those who have seen much of the suffering proceeding from such causes must be callous indeed if they do not feel indignant at these occurrences, especially in view of the comparative helplessness of the victims so far as obtaining relief or justice is concerned. Animals are protected from cruelty by good laws and a most beneficent society. Children find an able defender from imposition and cruelty in the society so rigorously and watchfully presided over by Mr. Gerry, but about the only recourse of women who are the victims of brutal violence is to swear out a warrant against the ruffian, which may mean nothing at all, or may mean his arrest and a fine or possibly a few months on the island, with plenty of food, comfortable quarters, and then, when the time is up, a return to the home to get as much as possible out of the wife and perhaps give her "a good beating" by way of "getting even" with her for having caused the arrest.

The amount of cruelty which is inflicted upon women in this city, to go no farther, is appalling. Within a month the papers have contained numerous accounts of the most barbarous conduct. One brute knocked his wife down in the very presence of a police magistrate, to illustrate his method. Another threw his wife down stairs. Another, after a long course of cruelty to his wife, ended by killing her and then killing himself. There is scarcely a physician in large general practice, especially if he goes much among the tenement houses (though cruel treatment of women is by no means limited to the poor or to the tenement houses), who could not narrate instances quite as revolting as those which have been noticed in the daily papers. Here is one subject about which hyperbole in the daily press is impossible. The writer himself has seen almost every form of brutal treatment to which devilish malignity could subject women—faces bruised and battered, bones broken, unborn infants killed or maimed as the result of kicks inflicted upon the pregnant, serious pelvic inflammatory troubles excited and requiring dangerous surgical operations for their relief. The community at large stands aloof alike from these victims and from the brutes who are the cause of their suffering.

The present is a good time for the medical profession to take up the cause of the injured.

What of the men who commit these crimes?

It may be said that their evil deeds are always committed under the influence of liquor. Well, what if they are? That makes it no easier for the victims; besides, as a matter of fact, this is not true. The men who do such things are as a rule bucolics and cowards who are only one degree more cruel and brutal when drunk than when sober. How can such brutal natures be appealed to? Kindness and persuasiveness are usually lost upon them. There may be some exceptions. Judge Stephen, in his History of the Criminal Law in England, says there are some men whose nature is essentially that of wild beasts. Their instincts teach them to prey upon and injure their fellow beings. In this class belong woman-beaters, and the same learned author thinks that the only way to impress them with a sense that they are doing wrong in inflicting pain upon others is by inflicting pain upon them. Argue as we may, the idea of punishment for wrong-doing can not be eliminated from society's regulations; to do away with it would mean anarchy.

The infliction of corporal punishment upon criminals of the class in question is indeed a measure which has dangers associated with it. If it is adopted, it should be surrounded with safeguards to prevent its abuse. That it can be done safely has been demonstrated in the history of the Elmira Reformatory, and in the laws and customs which prevail in the State of Delaware. So far as can be learned, the citizenship of Delaware has not become imbued by the retention of the whipping-post, and a gentleman from that State will be present at the meeting in question to give certain facts in regard to the workings of that form of punishment there. It is hoped that every physician who is in sympathy with this movement will be present at the academy to hear the arguments which are to be laid before the profession in favor of the proposed law.

MINOR PARAGRAPHS.

NEW MEDICAL JOURNALS.

If there are not quite so many first numbers as usual to make their appearance at the close of the year 1894, it must be said that those that have appeared are of uncommonly good quality. The Yale Medical Journal, published in New Haven,
more or less representative of the Yale Medical School, has been before the profession for a number of weeks, and must have made a favorable impression. It deserves to succeed, and we have no doubt that it will. Among the other initial or early issues that have since reached us are the Journal of Medicine and Science, described as the official organ of the Maine Academy of Medicine, a monthly published in Portland, edited by Dr. E. E. Holt and Dr. J. A. Spalding; the Colorado Climatologist, edited by Dr. Charles Manly and published monthly in Denver; the Leonceté, published by the students of the Detroit College of Medicine; the Intercolonial Quarterly Journal of Medicine and Surgery, a very handsome journal published in Melbourne; and a weekly journal of therapeutics, the Therapeutische Woehenschrift, edited by Dr. M. T. Schnirer and published in Vienna.

All the publications we have mentioned seem to have been started after due consideration and careful preparation, and we can not better commend them than by saying that we wish them a degree of success commensurate with their merits.

A MISTAKE IN ANATOMY.

In our issue for May 19th, on page 637, we published, under the heading of A New Sign of Lead Poisoning, an abstract from the Presse medicale in which the expression "the articulation of the manubrium with the ensiform cartilage" occurred. Quite recently Dr. George W. Wells, the editor of the Medical Examiner, has very kindly written to inform us that a number of journals, including his own, have copied the error without having observed it. We are glad to be able to say that the mistake was not ours, although we ought to have noticed it. In the French journal from which our abstract was made the phrase reads "l'articulation du manubrium avec l'appendice xyphoide." Of course, the gladiolus was meant instead of the manubrium.

CORSICA AS A WINTER RESORT.

Dr. Weslow W. Skinner, formerly of New York, has, as we announce under the heading of Changes of Address, recently taken up his residence in Ajaccio, Corsica. Dr. Skinner writes to us that Ajaccio is "a lovely winter resort, better for patients than the Riviera, if they are after quiet, freedom from dust, and sunshine." The place, we learn, is to some extent resort to by American invalids.

THE NEW HEALTH OFFICER OF THE PORT.

The appointment of Dr. Alvah H. Doty to be health officer of the port of New York gives general satisfaction to the members of the medical profession. Dr. Doty's long and useful career in the service of the city board of health and in the medical corps of the State militia gives promise of excellence in his administration of the more exacting office that he is now to fill. No better appointment could have been made.

ITEMS, ETC.

Lectures on Regional Surgery.—Dr. G. Frank Lydston will begin his third special course in regional surgery at the Masonic Hospital, Chicago, on Monday evening, the 7th inst., at eight o'clock. The lectures will be given every Monday evening. The subjects are: The Surgery of the Prostate, Bladder, and Kidneys, including Calculus; Appendicitis; The Surgery of the Rectum and Urethra; and Varicocele. The lectures will be illustrated by special charts and drawings.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Health Department for the following table of cases and deaths reported during the two weeks ending January 1, 1895:

<table>
<thead>
<tr>
<th>DISEASES</th>
<th>Week ending Dec. 23 Cases</th>
<th>Week ending Jan. 1 Cases</th>

The City Lunatic Asylums.—Last week the State Commission in Lunacy reported to Mayor Gilroy the results of its inquiry, undertaken at his request, into alleged abuses in the city asylums. The report concludes as follows: "It is a well-known fact that the degree of liberality displayed by representatives of the State in making appropriations for charitable purposes is always much greater than that shown by local authorities. In other words, experience has everywhere shown that the closer the relations between the appropriating power and the locality where the moneys appropriated by this power are to be expended for charitable purposes the more parsimonious the policy; and this fact has always proved detrimental to the welfare of the insane when under county or local control. As before stated, the conclusion of the commission regarding the evils which have been shown to exist in the New York city asylums is that they are largely, if not wholly, attributable to the system under which these asylums are operated, and that, however feasible in theory, in practical operation this system has been a failure, and fallen far short of the hope which has from time to time been entertained for it. As a system it has developed inherent difficulties and defects, which experience has shown to be ineradicable, even under the ablest management, and which make its operation in all essential particulars practically impossible. Such being the case, the commission would recommend that it be abolished, and that the policy of State care for the dependent insane of the city of New York be adopted at the earliest practicable date. It can not be said that the present system of county care has not had a fair trial, and this, too, under exceptionally favorable conditions, as compared with any other instance of county care in the State, and yet it has failed to meet every reasonable or just expectation. If the system has been a failure from its inception, is it not reasonable to conclude that it is likely to be a failure for all time to come? Respecting the State hospitals, it is believed that most of them represent to-day all that is best in the present state of knowledge respecting the care and treatment of the insane, and that whatever other criticism may be passed upon them, it can not be said that their inmates are not comfortably housed, properly fed, sufficiently clad, provided with sufficient attendance, and given proper medical supervision and care. The adoption by the city of New York of the policy of State care has been long advocated by the State Charities Aid Association, many of whose active members are thoroughly familiar with the workings of both systems and the results attained by each, and with their views upon this subject the conclusion in lunacy is in full accord. The principle of State care for the dependent insane represents the most intelligent and humane thought upon the subject at the present time, and it is to be hoped that the local authorities in the counties of New York and Kings, who are responsible for the matter, will not long hesitate in taking the necessary steps.
for the complete consummation of this policy by availing themselves of the opportunity extended to them in the State care act."

The New York Academy of Medicine.—At the last regular meeting, on Thursday evening, the 3d inst., a paper was to be read on The History of the Treatment of Spondylitis and Scoliosis by Partial Suspension and Retention by means of plaster-of Paris Bandages, and the Present Status of this Plan of Treatment before the Profession of the World, by Dr. Lewis A. Sayre.

At the next meeting of the Section in Genito-urinary Surgery, on Tuesday evening, the 8th inst., there will be a presentation of cases, pathological specimens, and new instruments. A paper entitled Latent Gonorrhea in the Female will be read by Dr. W. R. Pryor.

At the next meeting of the Section in Pediatrics, on Thursday evening, the 10th inst., cases will be presented, and Dr. Henry Koplik will read a paper on The Milk Supply of New York and its Availability for Infant Feeding.

At the next meeting of the Section in General Surgery, on Monday evening, the 14th inst., a paper entitled A Sublateral Triangle and its Surgical Importance will be read by Dr. Ramon Guiteras. There will be also a presentation of patients and an exhibition of pathological specimens, new instruments, etc.

The treasurer's report for the year ending December 15th says: "Evidences of broader influence, of higher attainment, of greater stability, must gratify observing friends of this academy. The work which depends upon your contribution to the treasury has not been allowed to wane. Receipts and expenditures for the library and general advancement are larger than during any previous year, notwithstanding the great financial depression, which physicians have keenly felt. The bureau for nurses has been self-sustaining and added something to the treasury. Three hundred and fifty-eight nurses have been registered, and one hundred and eighty calls for nurses have been responded to. Number of resident fellows, 774; number added during the year, 40; lost by death, 8; by removal and suspension, 15. There are now 60 non-resident fellows, 40 corresponding fellows, 7 honorary fellows, and 9 benefactors."

Changes of Address.—Dr. Francis W. Murray, to No. 32 West 29th Street, New York; Dr. Winslow W. Skinner, formerly of New York, to No. 32 Cours Grandval, Ajaccio, Corsica.

Army Intelligence.—Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from December 20 to December 29, 1894; Gleixnan, James D., Captain and Assistant Surgeon. The order assigning him to duty at Fort Snelling, Minn., is revoked.

Shaw, Henry A., First Lieutenant and Assistant Surgeon. The order assigning him to duty at Fort Niagara, Nebraska, upon the abandonment of Fort McKinney, Wyoming, is so amended as to direct him to report for temporary duty at Camp Merritt, Montana, and upon the completion thereof to proceed to Fort Snelling, Minnesota, for duty at that post.

Kennedy, James M., First Lieutenant and Assistant Surgeon, is granted leave of absence for one month on surgeon's certificate of disability, with permission to leave the limits of the department.

White, Robert H., Major and Surgeon, is granted leave of absence for a month, to take effect about December 24, 1894.

Society Meetings for the Coming Week:

Monday, January 7th: New York Academy of Sciences (Section in Biology); German Medical Society of the City of New York; Morrisania Medical Society (private), New York; Brooklyn Anatomical and Surgical Society (private); Corning, N. Y., Academy of Medicine; Utica, N. Y., Medical Library Association; Boston Society for Medical Observation; St. Albans, Vt., Medical Association; Providence, R. I., Medical Association; Hartford, Conn., Medical Society; South Pittsburgh, Pa., Medical Society; Chicago Medical Society.

Tuesday, January 8th: New York Medical Union (private, election); New York Academy of Medicine (Section in Genito-urinary Surgery); Kings County, N. Y., Medical Association; Medical Societies of the Counties of Brooke (quarterly—Binghamp ton), Chenango (annual), Clinton (annual—Plattsburgh), Erie (annual—Buffalo), Genesee (semi-annual—Batavia), Greene (quarterly), Jefferson (annual—Watertown), Livingston (semi-annual), Madison (semi-annual) Oneida (quarterly—Utica), Ontario (quarterly), Oswego (semi-annual—Oswego), Rensselaer (annual), St. Lawrence (annual), Schenectady (annual—Schenectady), Schuyler (annual), Steuben (semi-annual), Tioga (annual—Owego), Wayne (semi-annual), and Yates (semi-annual), N. Y.; Newark, N. J., Medical Association (private—election); Trenton, N. J., Medical Association (private); Clinical Society of the Elizabeth, N. J., General Hospital and Dispensary; Northwestern Medical Society of Philadelphia: Practitioners' Club, Richmond, Ky.; Norfolk, Mass., District Medical Society (Hyde Park).

Wednesday, January 9th: New York Surgical Society; New York Pathological Society (annual); American Microscopical Society of the City of New York; Metropolitan Medical Society, New York (private); Medical Societies of the Counties of Albany, Dutchess (annual—Poughkeepsie), and Seneca (semi-annual), N. Y.; Tri-States Medical Association (Port Jervis, N. Y.); Hampshire, Mass., District Medical Society (quarterly—Northampton); Worcester, Mass., District Medical Society (Worcester); Bennington, Vt., and Hoosick, N. Y., County Medical Society (annual—Albany, Vt.); Kansas City Ophthalmological and Otological Society; Pittsfield, Mass., Medical Association (private); Philadelphia County Medical Society.

Thursday, January 10th: Society of Medical Jurisprudence and State Medicine, New York; Brooklyn Pathological Society (annual—election); Medical Societies of the Counties of Cayuga and Fulton (annual—Johnstown), N. Y.; South Boston, Mass., Medical Club (private); Pathological Society of Philadelphia.

Friday, January 11th: New York Academy of Medicine (Section in Neurology); Yorkville Medical Association, New York (private); Brooklyn Dermatological and Genito-urinary Society (private); German Medical Society of Brooklyn; Medical Society of the Town of Sangertown, N. Y.

Saturday, January 12th: Obstetrical Society of Boston (private); Worcester, Mass., North District Medical Society.

**Births, Marriages, and Deaths.**

**Married.**

Summers—Hill.—In St. Matthew's, S. C., on Thursday, December 27th, Dr. George Summers and Miss Rosa Hill.

**Died.**

Detmold.—In New York, on Wednesday, December 26th, Dr. William Detmold, aged eighty-six years.

Kurtzman.—In New York, on Monday, December 31st, Dr. Edward J. Kurtzman, aged twenty-four years.
Letters to the Editor.

APOCYNUM CANNABINUM.

FORT WINGATE, NEW MEXICO, December 23, 1894.

To the Editor of the New York Medical Journal:

Sir: The interesting letter of Dr. Rollin B. Gray on Apo-
cyrum cannabinum, published in the New York Medical Journal of December 15, 1894, in which he traces back the use of this remedy to the Catararung Indians, leads me to send the following account of its medicinal use among the aborigines of to-day.

This plant still maintains its right to the popular name of Indian hemp, as it is in common use among the Sioux Indians of Dakota and Montana and the Cheyennes in Indian Territory. These Indians use the plant in the treatment of various maladies, but its pre-eminent value in their eyes consists in its virtue as a cure for the bite of the rattlesnake. For this most serious and not uncommon incident of life on the western plains they maintain that it is a never-failing cure. How much truth there may be in their assertions I can not say, but hearing from different sources, season after season, remarkable stories of the successful treatment of rattlesnake bites by Indians, I was led to investigate the means employed. My efforts were successful only after a large expenditure of time and patience, as well as coffee, sugar, and tobacco.

The root was generously given me, and the manner of its use freely explained, but no one would point out the growing plant. The rank and file of the Indians asserted that no one except the "medicine man" knew; and he maintained that he might only impart his knowledge to his successor in office when his time should come.

Several seasons passed before I became sufficiently intimate with one of the wise men to induce him to reveal his secret and bring me the mysterious plant whose greenish white flower I recognized as that of Apo cynum cannabinum. The plant is common along the banks of streams from Dakota to Texas.

The root of the plant is used, either freshly gathered or dried. The wound made by the fangs of the snake is first cut and scarified until it bleeds freely, when it is thickly covered with the scraped or powdered root bound on by a piece of well-greased buckskin. A quantity of the dry powdered root (about 260 mgs. for a child, and 390 mgs. for an adult), infused for ten or fifteen minutes in a little hot water, is then given internally. The dressing of the wound and the powder taken internally are repeated every twelve hours for two days. "Third day, bite gone," in the words of one of my informants.

If the fresh root is used it is scraped and applied locally as before, while for internal use an infusion is made by putting about an ounce of the root, cut into small pieces, into a pint of hot water and letting it stand for an hour or more, or until it acquires a milky appearance. The quantity of this given at one time is from two to three ounces. While they are preparing the medicine, many incantations, said to be essential, are performed.

The dose of the powder given internally I was at first disposed to look upon as rather an uncertain quantity, it being two pinches for a child and three for an adult, but upon carefully weighing a number of "pinches" they were found remarkably uniform in size, scarecly varying from 130 mgs. (2 grains) each.

Some of the cases reported were apparently well certified. The agent of the Yanktonais (a tribe of the Sioux) described to me a case occurring under his own observation in which a girl about twelve years of age was bitten on the arm by a rattlesnake and recovered within a week under the treatment of the Indian "medicine man." Other tribes may make use of Indian hemp, but my observations have been made only among the Indians mentioned above, the Cheyennes and the numerous tribes of Sioux.

James P. Kimball, M. D.,
Major and Surgeon, United States Army.

THYROID EXTRACT.

New York, January 1, 1895.

To the Editor of the New York Medical Journal:

Sir: On December 24th the New York representative of Parke, Davis, & Co. wrote me a letter the important part of which is contained in the following lines of information and warning:

"I have recently heard of the complaint made by yourself against the extract of thyroids. My house have written me that they very much regret your action in having sent this product to some of your friends in Europe, since they have never made any claims for it, in fact believe it to be perfectly worthless. However, there has been a certain demand for it, and they have been obliged to put it on the market. The product, you know, was made after the Hammond process, and the demand made by the great advertising given to it by the company handling the Hammond product. Now that my people know that it is not only worthless, but subject to putrefactive changes, they have ceased to manufacture it."

The letter from which this literal extract is herewith given was no reply to any of mine, nor does it claim to be confidential. It is full of interest, and very suggestive.

A. Jacobi, M. D.

THE LOCAL EMPLOYMENT OF COPPER ARSENITE.

1411 Walnut Street, Philadelphia, December 24, 1894.

To the Editor of the New York Medical Journal:

Sir: Referring to the article by Dr. A. Hrdlicka, on the local use of copper arsenite, which appeared in a recent issue of your valued journal, and to the attention which this report has received at the hands of medical editors, I beg to submit some additional notes on this important remedy. As a preliminary, however, it will not be out of place here to claim priority in the local employment of the drug, the following notes being extracts from The Pocket Pharmacy (D. Appleton & Co., 1892), which I prepared in the autumn of 1891.

The object of this little work was to record a number of important clinical facts which I might be able to elaborate more fully at a later period.

Directions are given for the preparation of solutions of copper arsenite, as follows:

"When used in the form of cyanure, a single tablet containing one grain of the drug is added to a pint of boiled water, and to this mixture sufficient diluted hydrochloric acid is added drop by drop to effect solution, by which we obtain, in fact, a chlorarsenite-of-copper solution. For use in the mouth and nares and for vaporization in the treatment of tuberculous, a solution is prepared by adding one tablet containing a grain to four ounces of boiled water, and sufficient diluted hydrochloric acid to make a clear solution; it should be passed through a filter to remove any sugar of milk or arsenious acid which may remain as a sediment.

"Experimental. made with acetarsenite of copper, which is more readily soluble than the arsenite, proved unsatisfactory, owing to the precipitation of a considerable portion of arsenic
acid, while a solution of the chlorarsenite is stable, showing no indications of deterioration after several months. Each thirty minims of the solution carries approximately a sixty-fifth of a grain (one milligramme), and this amount may be used hypodermically in the treatment of tubercular affections every second day and also in typhoid fever, without danger of abscess or any untoward symptoms other than follow the use of medicaments in this manner.

The solution was recommended to be applied locally and taken internally in the treatment of aphthæ; in the form of a spray, after the preliminary use of hydrogen dioxide, in the treatment of asthma; also in the same manner for the relief of bedsores, to be followed by arsénil as a dusting powder; in the case of blepharitis, to be followed by the use of purified petrolatum containing a small percentage of paraffin; for the relief of cancerum oris; in the form of a spray three or four times a day, in acute nasal catarrh, and the same in the case of chronic catarrh; in certain stages of cholera, in the form of enemata; as an enema in cholera infantum and for cholera morbus; in the form of a spray or vapor, for croup and for diptheria; in the case of enteritis and membranous enteritis, in the form of enemata; in glanders it is recommended locally and internally; in gleet it is advised in the form of a solution three or four times a day, and also in gonorrhœa, glossitis, edema of the glottis, spongy gums, hay-fever, influenza, intertrigo, leukorrhœa, sore nipples, phthisis, proptosis ani, purpural fever, scarlet fever, scurvy, sneezing, when it occurs in connection with hay-ashma, stomatitis, uvalgalatitis, tympanites, and yellow fever.

In the case of Asiatic cholera and yellow fever, I have only advised its use on speculative grounds, and in all the other instances cited the recommendations are warranted from personal experience. In the form of a spray or by vaporization, it has certainly shown remarkably good results in the treatment of incipient tubercular affections in conjunction with the hypodermic administration. I now recall a most interesting case of chronic gonorrhœa with orchitis which came under observation in December, 1891. The patient had been under treatment for several months; there was a muco-purulent discharge and the left testicle had attained to the dimensions of a good-sized orange. He came to me from New York on the way to his home in one of the Southern States and recovered fully in less than ten days. For the orchitic involvement the local treatment consisted in the application of ointment of red iodide of mercury (1 to 10 of benzoinated lard) and the addition of a suitable suspensory bandage.

From the foregoing it will be observed that the arsenite of copper has a wide range of usefulness, although these are only such as I saw fit to include in my little book written in the latter part of 1891.

John Aulde, M.D.

Proceedings of Societies.

AMERICAN NEUROLOGICAL ASSOCIATION.

Twentieth Annual Meeting, held in Washington, May 30 and 31, and June 1, 1894.

The President, Dr. B. Sachs, of New York, in the Chair.

(Conged from page 563.)

Crossed Knee-jerk.—This was the title of a paper read conjointly by Dr. Guy Hinsdale and Dr. J. Madison Taylor, of Philadelphia. It was based on studies of over a thousand cases of nervous diseases observed at the Infirmary for Nervous Diseases, Philadelphia, and at the institutions for the Feeble-minded at Elgin, Pa., and Vineland, N. J. In using the term crossed knee-jerk, it was meant that the patella tendon being struck, the opposite leg was instantly made to approach its fellow; hence the phrase "in-knee-jerk" or "contralateral knee-jerk" might be used to describe this action. The movement observed in the limb opposite to that in which the patella tendon was struck was not an extension of the leg so much as an adduction of the thigh (vastus internus and eraneus). The best attitude for eliciting the movement was that which permitted the freest knee-jerk, such as sitting on the edge of a table, or at least with the legs hanging down from a sufficiently high chair. It demanded rather more ease of lateral motion of the thigh. This was accomplished very well by seating the subject at ease in a chair, with the body erect and the knees ten or twelve inches apart, with the knee-joint at rather an obtuse angle, the feet being advanced a few inches. The phenomenon was observed in a small proportion of normal persons, and in from twenty to thirty per cent of the patients coming to a clinic for nervous diseases. It was distinctly proved not to have been due to a communicated shock or jolt to the pelvis by reason of its absence in all cases of locomotor ataxia, and its production in favorable cases on suspending the subject from the floor and observing the adduction of the thigh on tapping the patella tendon or, as in one case observed, tapping the tendon Achilles.

Crossed knee-jerk was also found to be re-enforceable. Tracings were shown which had recorded in a normal subject an adduction in crossed knee-jerk of a sixteenth of an inch; in a spastic, a quarter of an inch, and in the latter case, under re-enforcement, half an inch. Re-enforcement produced the movement in some cases where it was not otherwise evident. A case was related in which a very slight tap on the patella tendon had caused violent contractions of both legs, causing the knees to knock together or to cross over; a smarter tap would cause, in addition, the crossing of both arms in a sort of lock spasm, requiring aid afterward in stretching out the limbs.

The reflex are involved in movements of this kind was held to embrace the cerebrum.

Dr. H. R. Stedman, of Boston, asked if this condition had not been somewhat similar to the so-called allelochiria.

Dr. Walton thought that a practical result bearing on diagnosis could not fail to follow careful and systematic investigation of these anomalous reflexes. We had not exhausted the directions in which the reflex impulses might be deflected. He had found not only the classical reflex, recently described by Remak, of toe flexion on stroking the inner side of the thigh, but had seen both dorsal and plantar flexion of the toes on stroking various areas in the extremities in cases of broken back.

Dr. Morton spoke of the application of faradism to the right sciatic nerve as having produced a reaction in the muscles of the left shoulder.

Dr. George W. Jacoby referred to a paper read by him a few years ago, in which he had called attention to the phenomenon of irradiation of the electrical current.

Dr. Mills believed that the best explanation would be forthcoming from a careful study of the distribution of cells fibers in the cord and their relation to other parts of the system.

Dr. President considered the title of the paper an unfortunate one, and did not look upon this phenomenon as a crossed knee-jerk at all, but as a contralateral muscular contraction. He thought its reflex character was quite doubtful, and that there was no difficulty in accounting for irradiation on anatomical grounds.
Trehpinning among the Ancient Peruvians.—Dr. Der-cum, of Philadelphia, exhibited a skull which had been kindly loaned by Mr. Bailey Willis, of the Geological Museum. It belonged to the Peruvian Government, and its origin had been traced to prehistoric times. It was shown as an illustration of the ancient method of trephining.

Recurrent Oculo-motor Paralysis.—Dr. Knapp, of Boston, read a paper with this title, in which he related the case of a man, forty-one years old, who had had nervous heredity and severe neuralgic pain over the left eye, with ptosis, external strabismus, and numbness of the face, a year before he had come under the speaker’s observation. This had lasted seven weeks. In December, 1892, one year later, he had had intense pain in the left side of the head, with nausea and vomiting. There had been complete paralysis of the left third nerve, with anesthesia of the nose and cheek on the left side, and parasthesia of the forehead. Photophobia had been present. The anaesthetic region had been extremely tender on pressure, and there had been an increased discharge from the left nostril. After two weeks the paralysis had begun to diminish, and after four weeks it had almost wholly disappeared, but the sensory symptoms had still continued in a lesser degree. Statistics were then given of forty cases, and of ten other cases of a doubtful nature. In only six cases had there been complete recovery from the paralysis in the interval between the attacks, and in four more the pupil had remained dilated. In seven cases there had been at first complete recovery, but in the later intervals there had been some paresis. Senator’s division into periodical and periodically exacerbating cases had hardly seemed warranted, and, although some of the cases resembled migraine, the affection in most cases, if not in all, was not like migraine. Three autopsies had shown lesions involving the nerve, and most cases were probably due to such.

Dr. Mills had observed several cases of recurrent oculomotor palsy with involvement of the fifth nerve. He had also seen cases of recurrent facial paralysis. The only probable explanation in most of these cases was that of organic lesion. He thought Dr. Knapp’s cases had probably been due to a lesion of the root fibers. Dr. Monroe Prince agreed with Dr. Knapp in believing that these cases had been caused by organic lesion. He believed that pain, as a localizing symptom, possessed very little value. He would rather depend upon motor and sensory paralysis.

Dr. Walton thought all cases should not be classed together. While many were of unclear or basal origin, possibly some of the less grave cases were due to recurring edema, or perhaps vascular disturbance at the cortex, which would probably explain the coincidence of motor and sensory disturbance. It might be that some cases were allied to the severe form of hysterical spasm.

Dr. Knapp said that there was no case of complete recovery on record where there had been both motor and sensory involvement. In cases of syphilitic origin, where only one or two branches were involved, it was more likely to affect the nerve after it had left the pons.

Circumscribed Softening of the Pons Varolii and, in the Same Case, of the Internal Capsule, Caudatum, and Lenticula.—Dr. Charles K. Mills and Dr. John Zimmer presented a paper on this subject in which they stated that this case showed two limited lesions of unusual interest—one in the pons, and the second involving the internal capsule and a small segment of the caudatum and lenticula. The patient, a woman, forty-two years old, had had a previous history of alcoholism and of acute articular rheumatism. Examination had shown slight impairment of mental action, marked somnolency, and imperfect articulation. At rest, the right eye had turned strongly to the right, while the left had not been deviated. Both eyes could not be turned together to the left. The lateral movement of the left eye to the right had also been impaired, and slight nystagmus of both eyes had been present. The lids of the left eye could not be brought fully together. Right facial palsy had been present, but the tongue had not been deflected. Tendon and muscle phenomena had been much exaggerated in the parietal limbs. Anasthesia could not be discovered in any portion of the body. About eleven days after admission she had had a second epileptoid attack. She was then totally unable to articulate, but understood what was said. She was also unable to expectorate, and there was interference with swallowing. A thorough and careful autopsy made by Dr. Guiteras had revealed a circumscribed softening of the pons. The lesion at its cephalic extremity had reached to within 1.5 millimetres of the ventral surface of the pons, laterally extending to the rhaphes, and about the middle of the pons slightly across the mesial line. The area of softening had become smaller and more deeply situated as it approached the postoblongata, which it almost, but not quite, reached. The second lesion had been revealed by a vertical transverse section of the right basal ganglia and capsule. The widest portion of the lesion had corresponded to the plane of the cephalic extremity of the thalamus. It was about seventeen millimetres in its antero-posterior extent. The pontine lesion had probably involved the root fibers of the abducens, and the fibers connecting it with the facial fibers or nucleus. The position of the lesion had been such as not by any possibility to involve the cell nests of these nerves. The lesion had involved the cranial portion of the pons, including a portion of the pyramidal tract and the deep transverse fibers. The lesion of the internal capsule had been beautifully localized near the genu, probably involving the geniculate and speech tracts.

Lesion of the Thalamus. Death from Intestinal Haemorrhage.—This paper was read by Dr. Wharton sinker, Philadelphia. He referred to the importance of placing on record all facts relating to the function of the thalamus, and stated that his attention had been drawn, in connection with the case which he reported, to the observations of Lussana, Brown-Séquard, Elstein, and Schiff many years ago, in which they had produced ecchymoses and hemorrhages into the mucous membranes of the stomach and colon of some of the lower animals by wounding the corpora quadrigemina and optic thalamus.

The patient was a man, sixty-seven years old, who had worked for many years in a stone quarry, and had received frequent slight injuries to the scalp, in consequence of being struck by fragments of stone.

In July, 1892, after having been exposed to the sun, he had suddenly been taken ill, and had had to be removed to his home while in an unconscious condition, where he had been seized with convulsions, which had lasted for the greater part of two days. After a month he had been able to resume his work; but two weeks later he had begun to have epileptoid convulsions, which had recurred at irregular intervals of from one to two weeks. The seizures had always been preceded by an olfactory aura, the patient having observed the smell of burning sulphur. After a few months the patient had had maniacal attacks after his fits, and had been removed to the Philadelphia Hospital in December, 1893.

There had been nothing notable about his condition, except that the attacks of epilepsy had been of the convulsive form. He would run violently, and imagined that he was pursued by devils. Toward the end of February he had had an attack in which there had been rise of temperature, apparently without any physical reason. His intellectual powers had failed, and he had gradually fallen into a somnolent condition, which had lasted for nearly three weeks, at the end of which time he had suddenly and without premonitory signs been seized with
tostial hemorrhage of a profuse character, from which he had
died in about twelve hours.

At the autopsy the mucous membrane of the colon had been
found to be softened and deeply injected, but no lesion had been
found in the way of an ulceration or rupture of a vessel which
would account for the hemorrhage.

The brain had shown very marked evidence of an old lepto-
meningitis over the left hemisphere, and there had been athe-
roma of the vessels of the base. In the posterior right thalami-
there had been found a small area of softening. It was about a
third of an inch in length by a fourth of an inch in its transverse
diameter. No other coarse lesion could be found in the brain.

Cerebral Hemorrhage; its Cause and Premonitory Sympt-
omes.—Dr. C. I. Dana, of New York, presented this paper
and a report of a hundred consecutive cases of apoplexy with
hemiplegia observed at his clinic at the Post graduate Hospital,
also seventy nine cases of apoplexy with autopsy observed in
Bellevue Hospital. Thirty of the latter had come under his
personal care and observation.

Of a hundred non-fatal cases, thirty-six had been due to
syphilis. The special characteristics due to syphilis were that
they occurred in early life; they were often multiple in char-
acter, and the pathological condition underlying them was usu-
ally a thrombosis and softening.

So far as his experience and records went, cerebral hemor-
rhages were rarely repeated, and it seemed as if in many cases
the rupture of an artery had changed the vital conditions, as it
certainly did the personal habits, so that the attack exercised
a conservative influence upon the individual and actually tended
to prolong life.

Dr. E. D. Fisher, of New York, read a report of seventy-
seven cases. Fifty-one patients had had one attack, sixteen
had had two attacks, nine had had three, and one had had
six. All were still living. These cases had been observed in
his service in the City Almshouse. The average age at which
the first attack had occurred was about forty five years. His
observations, he thought, confirmed what had been said by the
reader. The longest duration since the attack had been
twenty-two years.

Dr. Gray, of New York, thought that the fatal defect in the
paper was that many things were confounded. It told us
nothing as to the frequency of apoplexy, but left us in doubt as
to the elements of diagnosis.

Dr. I. Weir, of New York, said that, while he believed
Dr. Dana's deductions from his own cases were of value, those
from other sources did not seem to him to be applicable.

Dr. William A. Hammonds doubted whether life was in any
way protected by an attack of apoplexy, as the same causes
would persist.

Dr. Sinkler had observed a case in which the attack had
occurred twenty five years ago. The patient did not seem to
be in any way benefited in his general condition.

Dr. Prince thought the fallacy lay in the statistics as to
those still living, as one could not say how many attacks they
were going to have.

Dr. Dana said it was hardly fair to criticise his dada, as suffi-
cient time had not been permitted for the reading of his entire
paper.

Lumbar Puncture for the Removal of Cerebro-spinal
Fluid.—This was the title of a paper by Dr. William Brown-
ton, of Brooklyn. He reviewed the main points in this recent-
ly devised operation. Brief notes of a few cases were given, as
well as directions for its performance. The following conclu-
sions were reached:

1. The method was simple, easily practiced, and rather

2. In itself it was usually without danger.

3. By it we certainly could draw off cerebro-spinal fluid.

4. The quantity removed at short sittings had been from
one ounce to one and a half in adults.

5. This without doubt represented the amount of free fluid
usually present in the lower vertebral canal even when oc-
cluded above.

6. In internal hydrocephalus the relief, if any, was but very
temporary. In the common form due to tubercular mening-
itis the result was not worth the trouble, while in the closed
or succumbed forms it must rather do harm than good.

7. As a diagnostic means e. g., in suspected meningeal
hemorrhage—it was valuable. As an index of pressure it
might also be worth noting.

8. It was worth further trial (c) as a passing relief in
brain tumors not complicated by hydrocephalus; (b) as a sub-
stitute for trephining in progressive dementia; (c) in certain
spinal troubles; (d) and possibly as a means of applying
medication directly to the spinal meninges.

9. In conclusion it might be said that, while admissible in
all cases of brain pressure, there was as yet no establisbed in-
dication for this procedure except for diagnostic purposes.

Dr. Mills said that all operations of this kind were unphiloso-
phical and would accomplish nothing, as the fluid re accumu-
lated. The same might be said of hydrocephalus. Some good
might be done when the fluid was either blood or pus, other-
wise it was not indicated.

Dr. Dana had used this method in three cases of alcoholic
meningitis (in the so-called "wet brain"). Two patients had
recovered and one had died. In the adult the operation was
difficult. He agreed with Dr. Mills as to its indications and
utility, but he believed that the operation possessed, at least,
some rational foundation.

The Non-operative Treatment of Brain Tumors.—Dr.
Theodore Diller, of Pittsburgh, was the author of this paper.
The writer took the view that not all brain tumors which could
be localized should be operated on. He cautioned against re-
garding as successes those procedures which succeeded merely
surgically. The obstacles in the way of a complete success were
many, and the results were disappointing in spite of the rich and
growing knowledge of localization. Operations should not be
undertaken unless the patient was getting worse in spite of
medical treatment.

Dr. Stare spoke of the case of a man with a doubtful his-
tory of syphilis and all the symptoms of cerebral tumor. Its
localization had been a simple matter. Mercury had been
used and iodide of potassium had been given in doses of
three hundred grains daily. There had been a marked im-
provement in all the symptoms, and it had seemed to be a case
of recovery without operation. The patient had died suddenly,
and at the autopsy a cystosarcoma had been found without
any evidence of gunnionous infiltration.

Dr. Piticam believed we should operate only when there
were definite indications.

Dr. Sinkler mentioned the case of a man with Jacksonian
epilepsy and no history of syphilis. Two years later all the
symptoms of tumor had been present. Mercury and iodide
had been used, but he had become progressively worse. An
operation had been performed, but no tumor could be dis-
covered. The wound had healed well. Since then, the patient
had improved steadily in all symptoms.

Dr. Jacour said there was a class of cases presenting all
of the symptoms of tumor which got well without operation.
He cited the case of a man with many of the symptoms ex-
cepting optic neuritis, where he had been unwilling to make a
positive diagnosis. The Plasmodium malariae had been found.
in his blood and he had made a complete recovery under large doses of quinine.

The President stated that we had all been disappointed more or less in the results after operation. It might be our own fault on account of the delay in operating. He had had a similar experience to that of Dr. Starr. At the autopsy there had been found a typical glioma. The symptoms had entirely disappeared for several months. In another case with all the symptoms of tumor, lobide had been used, but all the symptoms had subsided after thorough mercurial inunction.

An Electrode for Use in Diagnosis.—Dr. W. M. Lessen- sky, of New York, presented an electrode which had been specially constructed with a view to its usefulness in diagnosis.

The Treatment of Convalescence and the After-care of the Insane.—Dr. Henry R. Stedman, of Boston, spoke of the dangers attending convalescence in insanity and the precautions necessary to prevent relapse or prolong remissions. General rules and advice regarding the prevention of insanity were not regarded even by predisposed subjects, and were practically of but little use. The case was different when once an attack of insanity had been experienced. Although in certain cases the proper conduct of convalescence was vital to mental health, the study of this period was confined to a few scattered suggestions in the works on insanity. Instances of abrupt recovery, with hardly any convalescent stage, were rare. Although it might happen in chronic cases, it occurred, as a rule, in those of short duration—notably convulsive insanity and the toxic and neurotic insanities. Lucid intervals or spurious convalescences differed of cn in no respect from genuine recovery, with the single and essential exception that the sleep did not improve, or was worse. This was a valuable indication in the prognosis of permanent return to reason. To the cardinal signs of convalescence should often be added the disappearance of decided fear of a return of the attack and dread of the stigma to follow. It was important to be informed regarding the normal and usual physical troubles of the patient, as their reappearance was another and valuable indication of recovery; also in regard to a knowledge of the sequence of immediate prodromata of an attack. They were often repeated in reverse order while the patient was getting well. Complete mental rest during menstrual epochs, so highly important at this time, was often disregarded, and application of the mind, even to a slight degree, in study or other work, was equally to be deprecated. Early discharge from the asylum, or from special care away from home, was to be advised against, as a rule, especially in cases of melancholia with a history of suicidal attempts, and after acute mania, the most exhausting form of insanity, and one which left the patient particularly susceptible to slight influences for a long time. On the other hand, we should frequently advise early removal in other cases convalescing from melancholia, particularly when homesickness was a marked feature and occasionally when there was refusal of food. Certain patients with mild mania, also paranoides who were independent in the asylum and actively opposed treatment, were studied by outside life. A change also worked well until its novelty had worn off. The first year or so after recovery was a very critical time. The reader gave a number of indications in special cases, and suggestions for prevention of relapse.

These remarks applied chiefly to well-to-do patients. An important branch of this subject was the means for the after-care of the pauper insane. There was practically no provision outside of asylums for this class, and practically little advice or other help was given these unfortunate on leaving asylums; while for the physically sick, on the other hand, there was abundant provision for their care during convalescence, and the discharged convict was greatly helped and encouraged by charitable societies for the purpose. Asylum physicians often hesitated to set certain patients, whose mental condition seemed to have so far improved as to make it useless to keep this class longer under care (and even some who had fully recovered), at liberty, for fear that, thus suddenly thrown on their own resources, without oversight or perhaps means of support, they would fall back into their old habits of life which had given rise to their insanity. This fact, and their delicate mental condition, often rendered them easy victims to designing people.

These and other reasons had led to the formation in France of protectives societies, called Societies of Patronage, under official auspices. Their duties were to aid convalescent or recovered pauper patients by gifts of money, clothing, tools, redemption of articles in pawn, payment of rent, admission to convalescent homes in cottages intermediate between confinement and complete freedom, or in hospitals or houses of refuge; securing situations for them, and finally their supervision wherever employed. This work continued during the first month or two after the patient's discharge. Similar societies or means of relief had been adopted in England and Scotland. They were described in detail. There was no better work on the score of both humanity and public economy than the adoption in this country of similar means for the prevention of insanity.

Dr. E. D. Fisler was of the opinion that patients left the asylum too early. In cases where they were oversensitive regarding their previous incarceration, something must be done to care for them and obviate a relapse. He was in favor of establishing convalescent homes for such patients, and spoke at length in confirmation of the views of the author of the paper.

Dr. Deneum thought this matter a very important phase in the care of the insane. It was, however, quite difficult to deal with individual cases. Where the element of exhaustion had been a prominent causative factor, the patient required detention and care much longer.

Dr. Starr was glad to know that Dr. Stedman favored the earlier removal of melancholies from asylums. One of the chief difficulties was in controlling the families who did not know how to manage the patient after his return.

Dr. Jones, of Minnesota, said that in Minnesota, since the word asylum had been changed to that of hospital, it had tended to remove any of the supposed stigma that had been usually attached to people who had been in institutions for the insane.

Dr. Knapp and the President concurred in the views expressed by the reader of the paper.

Dr. Dana said that the subject was of great economic as well as medical importance, and he would suggest that a committee be appointed to investigate the matter. This suggestion was then presented in the form of a motion, which was carried. The President then appointed as a committee Dr. Stedman, Dr. Dana, and Dr. Deneum.

A Suicide's Brain with Two Pistol-bail Wounds.—Dr. F. T. Wood, of Ithaca, exhibited a specimen and showed a dozen photographs of various aspects, and blackboard diagrams of the left side, and of a transverse section at the level of the fatal wound. W. J. B., a dentist, thirty-five years old, of Ithaca, N. Y., was found dead in his office on the 7th of April, 1884. A 0-22 revolver was clapped in his right hand. There were two bullet holes, one in the middle of the forehead and the other in the right temple, neither ball having emerged. In accordance with his written directions, the brain had been preserved in the museum of Cornell University as specimen 3,129. The first ball, presumably deflected by the skull, had passed endoventral to the cranial floor, and had been reflected dorso-caudal at nearly the same angle to a point just cephalad of the
precommisurate, where it had lodged, having merely abraded the mesial surface of the left frontal lobe. The second bullet had entered at the right subfrontal gyrus, passed obliquely sinistro-caudo-dorsad, had torn the callosal and intervening structures, and emerged in the central second left central fissure. As there had been no suspicion of foul play, and documents in the deceased’s handwriting had declared his intention to commit suicide, the case exemplified the possibility of two self-inflicted bullet wounds of one brain. The fissures presented many peculiarities. The most perplexing was the apparent coexistence of two central fissures on each side. The only two similar cases hitherto observed had been recorded by Giaconini and Calori. Suicide had been committed by a grandfather and one uncle, and attempted by another uncle.

Dr. Dancer had examined a large number of brains of the insane, but he had never seen such an instance as that presented by Dr. Wilder.

Dr. Dana said that he had no doubt that the anterior of the two fissures was the fissure of Rohdand. The interruption of this fissure on one side by a bridging convolution was extremely rare and very interesting. The brain had presented a unique fissuration. He could not understand how a primary fissure like the Rohdand could be doubled in any event, and was skeptical of the genuineness of reported cases.

Infantile Hemiplegia; Imbecility and Epilepsy; Craniotomy; Marked Improvement.—Dr. Edward B. Ansell, of Rochester, reported a case and read a paper with this title. He said that the salient features of the case had been a forereps delivery, succeeded by double ptosis, occasional tonic spasm of the right arm, and contracture and hemispasm of the right hand. Physical and mental development had been slow, and epilepsy, with from three to five seizures daily, had supervened three months prior to the operation. At the time of the examination the child was partly imbecile. The skull measurement had given a cranial index of 677; the palate was high arched, the teeth were jagged, and the right wrist and hand, which were much smaller than the left, were helpless. A diagnosis had been made of pressure in the neighborhood of the band center of the left motor area, due either to a hemorrhagic plaque or cyst.

Craniotomy had been decided upon as a tentative measure with a view of relieving the pressure and consequent symptoms, while avoiding the greater risk of opening the dura necessary to removal of the cyst wall. The operation had been performed on March 13th last, and upon removal of the trephine button a subdural hemorrhagic cyst had been found. The cranium overlying the cyst had become very much thinned, and had been freely cut away beyond the limits of the cyst. By an aspirating needle half a drachm of fluid had been removed, otherwise the dura had not been injured. The scalp incision had healed readily, but owing to an over-tight bandage edema had developed, and by the eighth day had caused sufficient pressure to develop a hard convolution and high temperature. With the remedying of this, marked improvement in all the symptoms had ensued.

Up to the present time (three months after the operation) there had been no recurrence of the epileptic attacks, while there had been a commensurate improvement in the mental and moral condition.

Dr. Mills considered it presumable that the cyst which had not been opened was a porencephalic cavity, and that opening and draining it would have been useless.

Dr. Putnam agreed with Dr. Mills. He said it was rarely possible to remove a cyst satisfactorily. In a case seen by him the cyst had been tapped and the drain left in. Improvement had followed.

Dr. W. A. Hammond spoke of two patients on whom craniotomy had been performed. One was eighteen years of age, and had become an imbecile as a result of an injury to the head. He had remained in this condition for four years. After an operation there had been an improvement at the end of two months. At the end of a year the improvement had been marked. In the other case of a similar character the operation had been followed by improvement.

The President said that cysts differed in character. The superficial cysts were due to meningeal hemorrhage during labor, and could be satisfactorily treated by operation.

Dr. Angell said this was not a case of porencephalus, but an arachnoid cyst from a meningeal hemorrhage.

Infantile Amyotrophic Lateral Sclerosis of the Family Type.—This was the title of a paper by Dr. Charles Henry Brown, of New York. He gave the history and report of a case. The disease had occurred in a boy fifteen years of age. There had been marked emaciation, particularly in the upper part of the body, and paralysis and atrophy of all the facial muscles, except those of mastication. Fibrillar twitches had been present all over the body. The superficial and deep reflexes had been active. Ankle clonus had been demonstrable. There had been double lateral curvature of the spine. Mentally, the boy was fairly bright. He cried readily and was amused at trifles. He was microcephalic, and acted and appeared like a child of ten. There were evidences of a general arrest of development. Dr. Brown considered his case as belonging to one of the family types of infantile progressive bulbar paralysis, plus the same implication that was found ingrained upon the progressive polymyelitis of adults which gave us amyotrophic lateral sclerosis. In muscular myopathies the respiration was not involved. The upper facial muscles were usually unaffected, and the “tapping mouth” was not observed. The atrophy was more irregular, more bilateral—that is, it was worse on one side. Electric reactions were not of special importance in the diagnosis. In some reported cases of infantile progressive bulbar paralysis they were normal; in others there was degeneration.

To place this case among the scapulo-humeral, or facio-scapulo-humeral, types of muscular atrophy was out of the question. Though the neck was much thinned, the scapulo-humeral group and the back muscles were generally the best the patient had. What muscles he did possess were active, and the exaggeration of reflexes, the fibrillar twichings, and the retractions of tendons that were present, though slight, precluded a peripheral origin of the disease. As far as was known, no case of the kind had ever been reported and diagnosed as infantile amyotrophic lateral sclerosis of the family type. Hoffman’s case, in a boy eleven years old, closely resembled it. Here, too, there had been marked labio-glossal laryngeal paralysis, great emaciation of the upper extremities, of the trunk extending down below the hips, together with exaggerated reflexes in the lower extremities and diminished reflexes in the upper. In Hoffman’s case the atrophy had probably been too extreme in the upper extremities to admit of much response. In all the cases reported of these bulbar diseases belonging to groups of family types there had been marked difficulty of respiration and special implication of the upper branch of the trisfacial nerve.

Dr. Knapp showed a microscopic specimen from a case of atrophic lateral sclerosis which had occurred in a man fifty years of age. The disease had progressed very rapidly, and he had died at the end of fourteen months of broncho-pneumonia. There had been no bulbar symptoms. The section presented had shown marked vascularity in the seleroseated portions of the cord.

Dr. Putnam reported an analogous case of bulbar paralysis in a young child.
Dr. Preston, of Baltimore, had seen the case of a child, two years of age, in whom spastic symptoms, such as exaggerated knee-jerk and ankle clonus, had developed soon after an attack of acute poliomyelitis.

Ingravescent Cerebral Haemorrhage Treated by Ligation of the Common Carotid Artery.—This was a joint paper by Dr. F. X. Demer and Dr. W. W. Kren, of Philadelphia. In the first case reported the symptoms pointed to a slowly progressive spastic hemiplegia lasting over three days before ligation of the common carotid had been resorted to. The symptoms had been steadily progressive, and threatened a fatal termination. Ligation of the carotid, as proposed by Mr. Horsley, had promptly arrested the symptoms, and the man had made an excellent recovery. Months afterward, merely symptoms of a spastic hemiplegia had persisted, but they had not been very marked. The second case had been one in which the symptoms pointed to a progressive hemiplegia lasting eight hours. The patient's condition had been so grave at the time of the operation that little had been hoped from it, and indeed it had proved useless, the patient dying several hours afterward.

Dr. Dercum pointed out that the class of cases in which benefit was to be hoped for from ligation of the common carotid were those in which the haemorrhage was decided ingravescent in type. He also dwelt upon the difficulties of a diagnosis between haemorrhage and thrombosis in such cases, and pointed out that, even in cases of an error in diagnosis, it could not be said that the operation involved additional risk to the brain. Finally, he suggested that, instead of ligation of the vessel, the expedient of compression of the common carotid should be tried in every case of apoplexy as soon as the physician arrived. A surgeon was not always at hand, and besides, compression of the carotid was so simple a procedure that a bystander could easily be instructed to apply it.

Dr. Frank Fry, of St. Louis, knew of several instances in which the operation had been done. All had proved fatal. He believed that none of them had been indicated or justifiable.

Dr. Knapp believed that the neurologist did not see the case until it was too late to make a satisfactory diagnosis.

The President thought the chief difficulty was in diagnosis, and that the haemorrhage was usually a self-limited one.

Dr. Dercum said that the operation was only indicated when the diagnosis of ingravescent apoplexy was definite.

Merycism.—This was the subject of a paper by Dr. W. A. Hammond, of Washington. He defined this condition as the occurrence of rumination and remastication in the human subject. About fifty cases only had been reported. Several cases were referred to, among them that of the distinguished physiologist, Dr. Brown-Séquard, who had acquired it as the result of experiments performed upon himself. Another case reported was that of a young man whose mental condition had been impaired, and who had also been the subject of merycism. No special treatment had been undertaken against the merycism in this case, but the patient had been trephined with the purpose of improving his mental condition. There had been no unusual features connected with the operation, but it had been noticed that the regurgitation did not occur with the meals he had subsequently eaten until the fifth day, when there had been a slight return. Eight days later a similar button had been removed from the corresponding part of the left side of the skull. From that time (about ten months ago) to the present there had been no regurgitation. Whether the cure of merycism in this case had been directly due to the operations on the cranium, or the result of the mental improvement, was a question which it would be difficult to answer.

Dr. Knapp was unaware that so few cases had been reported in this country. Two cases had come under his notice. Both were in physicians in good mental condition. He thought a distinction should be made between congenital and acquired merycism.

Dr. Lloyd believed that some cases should be considered as a neurosis allied to hysterical vomiting, such as regurgitation from the oesophagus.

The President had seen a man who had conquered the habit by the exercise of his own will. His views were in accord with those expressed by Dr. Lloyd.

Dr. Hammond said that acquired merycism had always been due to overloading the oesophagus and to the bad habit of rapid eating. He was extremely doubtful as to its being a neurosis.

Chronic Chorea.—Dr. Lloyd, of Philadelphia, exhibited a large number of sections from the midbrain, pons, medulla, and spinal cord of a patient with chronic chorea.

New Inventions, etc.

AN AXIS-TRACTION FORCPS.*

By T. J. McGillicuddy, M.D.

With this instrument we can make ideal axis traction during the entire passage of the frontal head, with remarkable ease and safety.

1. In cases where much strength must be employed you can not perform axis traction properly with the common forceps by Pajot's, Smith's, or any other manoeuvre.

The advantages alleged for this instrument are:

1. That with its use axis traction is simple and uncomplicated.

2. That it is superior to Tarnier's in the fact that while using it axis traction at the superior strait is perfect.

3. That while in relation to Tarnier's instrument a great deal has been said of the indicator, in this forceps the indicator is in the hands of the operator and tells his conscience musculaire the direction of traction as well as the resistance.

4. That it does away with the trouble of Pajot's, Smith's, or other methods, and with its use one has plenty of power and perfect control.

5. That it is easier to make rotation in the posterior positions with the adjunct handles, if it is thought best to use the forceps for that purpose.

6. That it is easy of application, and in its dual character it has the advantages of axis traction and the ordinary forceps, and saves the expense of buying two instruments where one will do.

The Tarnier instrument is complicated, cumbersome, and expensive, thus nullifying its good points, if it has any, and has been condemned by the Paris Obstetrical and Gynecological Society for these reasons. Its theory may be very pretty and interesting for those who have not had much experience in forceps delivery, but practically it is a useless and harmful instrument.

No woman should be delivered except by axis traction, and with these axis-traction handles you can determine the exact amount of resistance and the proper amount of force to employ, and readily and easily use it.

* Remarks before the Section in Obstetrics and Gynecology of the New York Academy of Medicine, November 21, 1891.
Dr. Leishman, in writing of the long forces and high operation, says: “It is now very generally believed by those who have had the greatest experience that a large proportion of the unfortunate results depend upon improper instruments, and especially upon the use of such as are deficient in power. The observations which on this point I have already quoted from Dr. Barnes apply here with peculiar force. Power and control are correlative factors toward the attainment of the result which we desire, and if there is a deficiency in the former we can have but little confidence in the issue of the case.”

With this forceps we pull directly in the axis of the brim. One can not grasp the handles of the ordinary forceps with comfort with both hands and still make any great axis traction. Most physicians say that the hands become cramped and lose all their muscular power after pulling for a short time.

In cases attended with some difficulty, who has not seen physicians with their feet placed against the side of the bed or the buttocks of the patient, hanging on to the handles of the forceps and pulling away with all their strength while bathed in a profuse perspiration?

These violent exertions are entirely wrong and unnecessary, as the arms alone should be used, and the body placed in a position where the traction can be easily arrested if there is any slipping of the blades.

It is the improper use of the wrong kind of forceps that makes it such fatiguing and dangerous work.

**Miscellany.**

**Rheumatism of the Larynx.**—The December number of the *Edinburgh Medical Journal* contains an article by Dr. G. Hunter Mackenzie in which he remarks that it is only within a comparatively recent period that attention has been drawn to the manifestations of rheumatism in and about the larynx. It may be internal or external or both, with corresponding modifications of the symptoms. Dr. Ingalls, says the writer, defines rheumatic laryngitis as a “painful affection of the vocal organ attended by hoarseness and fatigue after talking, sometimes by grave obstruction of the glottis.” Or the commoner forms he says: “For some years I have observed chronic painful affections of the larynx attended by no erosions or ulcerations, and by little congestion or swelling. They usually occur in persons of rheumatic diathesis; but often the larynx or the tissues about the hyoid bone present the only evidence of the constitutional disease.” Thus says Dr. Mackenzie, the symptoms dependent upon rheumatic disease within the larynx may be of a somewhat grave nature. Vocal defects are, however, those most commonly met with, and are usually dependent upon immobility of a vocal cord, owing to affections of the muscles concerned in its movement. In such a case the laryngoscopic appearances may be entirely negative. If, however, the disease is arthritic, and the crico-arytenoid articulation is affected, there may be more or less severe laring and tautness of the mucous membrane over the arytenoid cartilages. It is of importance to note that laryngeal hemorrhage may be of rheumatic origin.

Outside the larynx, rheumatism most frequently occurs as a muscular affection, and manifests itself by pain on pressure and on movement of the affected muscles. This variety may be coincident with the internal affection, and is more apt to be accompanied by rheumatic manifestation elsewhere, especially in the muscles of the neck and shoulders. Dr. Mackenzie cites the following case as an illustration of internal and external laryngeal rheumatism: The patient, a man thirty years old, had been suddenly affected with huskiness, the onset of which was coincident with the development of rheumatic pains about the neck and shoulders, about six weeks before the author had seen him. Slight discomfort was present during deglutition, and tenderness on pressure was manifested in the region of the hyoid bone and of the thyroide cartilage. On laryngoscopic examination, there was found pharyngeal and respiratory immobility of the left vocal cord, which lay in the cadaveric attitude; there was puffiness over and about the left arytenoid cartilage. The voice was husky and easily fatigued. The patient was treated with stimulating inhalations and antirheumatic remedies. A year later the vocal cord still remained immobile, but the puffiness had disappeared, and the vocal symptoms had partially subsided.

Immobility of the vocal cord, with consequent huskiness, says the author, seems to be one of the commonest manifestations of rheumatism of the larynx. There is, he says, sufficient evidence to show that the internal and external muscles are subject to rheumatism; that the symptoms, although slight and rarely grave, may be the source of much uneasiness to the patient, and that the resulting vocal defects may be persistent and sometimes permanent. Further, this local affection may exist without additional evidence of the presence of the disease, more especially when the internal muscles of the larynx are alone affected.

The treatment of such cases, says Dr. Mackenzie, ought to be general rather than local. Very little benefit follows the application of pigments and similar preparations to the affected parts, whereas a course of constitutional antirheumatic treatment will almost invariably remove many of the disagreeable symptoms of which the patient complains. If, however, the crico-arytenoid articulation is affected, it is doubtful if the corresponding vocal cord will ever regain its normal range of movement, and the voice may be more or less permanently affected.

**The Antitoxine Treatment of Diphtheria.**—The *British Medical Journal* for December 15th contains an article on this subject by Dr. E. Klein, who remarks that the rationale of the method used by Roux for obtaining Belin's antitoxine seems to him difficult of acceptance from a theoretical point of view. This does not, of course, he says, imply that the serum which Roux obtains has not antitoxic powers; the chief difficulty of his method is, that horses require a very long and tedious series of numerous injections with enormous quantities of pure diphtheria toxine for the production of considerable antitoxic
power. "Large amounts of pure diphtheria toxin," says Dr. Klein, "are introduced over and over again into a horse which has already by previous injections of the pure toxin been rendered, to a certain extent, resistant against this toxin, that is to say, a horse that has by previous injections of diphtheria toxin become more or less resistant must possess a corresponding amount of antitoxine in its blood." But, since the two substances—namely, toxin and antitoxine—are antagonistic and neutralize one another, it follows that each successive injection of a large quantity of pure diphtheria toxin into a horse must neutralize a proportionate amount of antitoxine already formed and present in the animal's blood. These considerations Dr. Klein says have led him to adopt a different plan in the preparation of antitoxine serum from the horse, and the principle of his method is as follows: By a few injections of the attenuated living bacilli—the attenuation is due to age of the culture—along with their toxin into the horse, this animal is endowed with a certain degree of resistance. Then large quantities of living diphtheria bacilli—without their toxin—taken from the surface of solid cultures of gradually increasing virulence, are repeatedly injected subcutaneously, so as to allow the bacilli to grow and to multiply, and gradually to produce within the body of the animal the toxin and ultimately the antitoxine. Every such injection is followed by a temporary reaction and a local tumor, but there is no suppression at the seat of inoculation. As soon as the tumor disappears a new injection is made with large quantities of living bacilli scraped from the surface of solid media (agar-agar and gelatin). By the third week the animal will bear the scrapings from the surface of two whole agar-agar cultures of virulent character. If, after the first bleeding of the horse, it is again injected two or three times with virulent bacilli, the further serum obtained from such a horse possesses even increased antitoxic power. This serum, says the author, has been used on the human subject in cases of diphtheria, some of them very severe cases. It has been injected in doses of from five to eight or ten cubic centimetres, and in severe cases the injection has been repeated within twenty-four hours. The result has been highly satisfactory. In some severe cases it has been particularly striking, further spread of the membrane being entirely arrested, and rapid loosening and discharge of the existing membrane being also a conspicuous feature.

Idiopathic Dilatation of the Sigmoid Flexure.—The British Medical Journal for December 1st publishes a report of a recent meeting of the Clinical Society of London, at which Dr. W. P. Herringham presented the following case: The patient, a man seventy-eight years old, had been suffering for eight days with suppressed action of the bowels. At the end of that time the symptoms pointed to chronic obstruction. There had been a history of lifelong constipation and of a similar attack five years before, which had been overcome by a strong purgative. For the last six months his general health had been excellent, and the constipation has given place to regular action of the bowels. No stricture could be felt per rectum, or any tumor in the abdomen. There had been considerable distention, which seemed to involve the transverse colon. A diagnosis had been made of facial impaction or some non-inflam- matory stricture above the rectum. Attempts had been made for two days to relieve the obstruction by purges and enemata, but on the third day the patient had become worse and an operation was performed, during which feces were found in the peritoneal cavity. The patient died a few hours later. An enormous dilatation of the sigmoid flexure was found which covered almost the entire front of the abdomen. The inner surface was extensively ulcerated, and in several places it was black and gangrenous, and in others had given way, allowing of focial extravasation into the peritoneal cavity. There were old adhesions to the liver and to the omentum, and there was recent peritonitis. There had been no stricture and no mechanical cause could be discovered for the dilatation, which the old adhesions showed to have been of long standing. The intestines above and below the sigmoid flexure were natural.

Such cases, says Dr. Herringham, were extremely rare; only eleven similar cases could be found, three of which had been due to sigmoid dilatation. In one case fecal impaction had explained the condition, but in the others no sufficient cause had been found.

Thymol as an Anthelminthic.—The Lancet for December 1st publishes an article by Dr. Prospero Sosnino, of Pisa, in which he gives an account of his success with this drug in the treatment of ankylostomiasis. In this disease, he says, it often acts like a charm, although in some rare cases he has had difficulty in riddiving the intestines of the parasite by means of this remedy. In a case of this kind observed by him daily doses of sixty grains brought away in all thirty-one ankylostomata, nevertheless the stools contained eggs of this parasite in as great abundance as they had before the thymol treatment was begun. The author can not explain the cause of this, but thinks that it may be due to the circumstance that a certain number of worms are still hidden in the walls of the intestine or under the folds of the valvulae conniventes in such a manner that the thymol may pass them without displaying its deadly action. These rare cases, he says, must not detract from the reputation of thymol as an admirable remedy in the treatment of ankylostomiasis, but he insists that its efficacy does not in any manner warrant the profession in proclaiming it as a remedy against all other intestinal parasites without adducing positive proofs of such efficacy in the case of each species of worm. While the expulsion of ankylostomias is the rule with thymol, the drug acts on the other worms only exceptionally, and in the greater number of cases it altogether fails to effect their expulsion.

As for trichocephalus, says the writer, it is known that there is great difficulty in obtaining its expulsion by any remedy, but after his first trials he entertained the hope that the new drug might prove to be an efficacious remedy against this worm. The ordinary seat of the trichocephalus being the cecum, the author tried using thymol as an enema, but, as this meant that the thymol must be given in solution, he feared it could not be used in such doses as would be efficacious as an anthelminthic without proving hurtful by absorption, for thymol introduced into the circulation is certainly a poison, even in small doses. When large doses are given, it is administered in powders, and if it is ever absorbed, it will be only in the miniest amount. Vertigo and delirium are symptoms of its dangerous absorption; but they are met with only in rare cases after the administration of such doses as sixty grains.

With regard to the administration of thymol, the author thinks that the best way is to give it in powder inclosed in wafers or cachets. Taddele, he says, are not of any advantage, because they must be given in numbers too great for the convenient administration of doses of several grains, and the direct contact of the drug with the mouth may prove hurtful, as it is an acid.

The Hotel Doctor.—The following sketch, in far greater conformity to the facts than is common in newspaper articles on medical topics, appeared in the Sun recently:

"Most New York hotel's have a resident physician. He is known as the hotel doctor. He has nicely furnished apartments, all the latest instruments and books of his profession,
and is considered an important person. The resident physician at the Astor House, the Fifth Avenue Hotel, the Gilsey, the Imperial, the Plaza, the Windsor, and other hotels of the same grade, treat the most important men in political and business life. Their patients also include some of the richest women in America, and their sons and daughters. Many of the physicians of the hotels have been men of recognized ability, yet inquiry the other day developed the interesting information that the profession at large regards them with certain peculiar notions. Furthermore, it was made clear that there is no real bond of sympathy between a hotel physician and his transient patients.

"Professionally speaking, the life of a hotel doctor is not pleasant," one of them said. "Financially speaking, it has its advantages. Just how some physicians attract themselves to hotels is peculiar. The doctors who do this seem to be averse to enduring the early struggles of a young physician. We have all heard of young physicians in the country who spend their last dollar in hiring carriages in order to wheel madly through the town with the hope of impressing the residents with the size of their practice. There is method in such a course, and there is just as much method when a young physician in the city keeps his eye open for a hotel berth. As soon as this is found he gets together all his spare cash and hires a room in the hotel. He then gets permission of the proprietor to hang out his shingle.

"In many cases physicians who started in early life with a hotel berth, merely to get transient patients and avoid the dull and heart-aching waits for practice, have continued on at the hotel until they are old men. Yet there is always a pang in their hearts. They are like many old bachelors who look around them and see their friends surrounded by happy families. There is a dull longing in the hearts of these old bachelors on such occasions. Just so the hotel doctor looks on his brother physicians with steady practice in families that have learned to regard them with fondness and esteem. As these hotel doctors grow older they continue fond of their case. They do not have to go out at all hours of the night, in all sorts of weather. Their patients are right at hand, and there is little discomfort in their lives. Yet I never saw a hotel physician who lingered on in one berth until past the meridian of life who did not regret that he had not encountered the early struggles of young physicians, with the terrible grind, the anxiety for practice, and all the disadvantages of poverty, but with the knowledge that they are steadily climbing in their profession, and surrounding themselves with patients who become their truest friends.

"The hotel physician paused in his story and then intimated that the great physicians of New York city were rather inclined to look down upon the men of the same profession who reside in the hotels, or at least upon those who have passed most of their days as hospital physicians.

"These great physicians," he continued, "believe that we are actuated solely in our profession by money considerations. They do not believe that we have the profession at heart. They themselves believe in financial results, but the most of them aver that these are not the only considerations with them, and that they are students of every new feature in the profession for the profession's sake. They declare that we are not. If I had my life to live over again I would not be a hotel physician. I would go out and struggle, and have the regard and esteem of a class of permanent patients, and the honor that redounds to a physician in the broad field of his practice. I would advise all young physicians who begin a hotel career to continue in it only long enough to obtain money to keep them in the world until they can get a footing. We are not regarded as specialists or as great in any feature of the profession. We are simply at hand to attend to the passing ills of transient patients, who don't care a copper for us, and in whom we have only the ordinary professional interest. I cannot speak too much of the tender relations that exist between the family physician and his old patients. It is one of the beautiful things in life, and one in which we hotel physicians have no part. I have attended many of the greatest statesmen and many of the most beautiful and accomplished women in the United States, but I doubt if they even remember my name, much less my appearance, and neither do I believe that they recall the help I gave them when they were in pain and distress. It is far different with the family physician. The husband and wife are grateful to him in the majority of instances until their last hours. Their children, and, in numberless instances, their grandchildren, hold fast to the old doctor, and if the doctor has a son they fasten to him, and so it goes on. There is a tie of friendship. It is similar to the confidence many families place in the old lawyer.'

"In other ways the hotel physician meets with unpleasant experiences. Many guests dislike to call in a strange physician, and do so only when their condition makes it absolutely necessary. There seems to be distrust of a strange or hotel physician, and innumerable instances were related where guests at some of the largest hotels in New York have risked death in order to get back home to their family doctor. These instances hurt the hotel doctors' pride, both as men and physicians.

"The hotel physicians of New York, though, are pleased at the more kindly spirit they observe among hotel proprietors in the event of a death in the hotel. Only a few years ago the death of a guest in a hotel was followed by summary action on the part of the proprietors. The body was hurried out of the hotel as quickly as an undertaker could be summoned. The hotel physicians say that this practice brought about many deaths, for the reason that sick people took all sorts of risks in getting to their homes, dreading to die in a hotel. Now, however, the average hotel proprietor is all kindness on occasions of death. Everything is conducted very quietly, but he assures the relatives that there is no need for unseemly hurry in removing the body. Many times the preliminary funeral services are conducted in the hotel.

"But this is a story about hotel physicians and their chances of fame and fortune. It is the advice of one of the oldest hotel physicians in New York city that young men starting in life would be far better off in the end if they took to the woods and built up a practice, instead of becoming hotel physicians and living in comparative ease and comfort, but without any of the real blessings of the profession."

Serum Therapy in the Treatment of Diphtheria.—At a recent meeting of the Paris Société médicale des hôpitaux, a report of which appears in the Médecin médical for December 12th, M. Moisard gave an account of his observations among two hundred and thirty-one children who had been treated by this method during the months of October and November. Out of this number thirty-four had died, making the mortality 14.71 per cent., which, he says, is very much lower than that indicated by M. Roux in a recent communication, twenty-six per cent. The author thinks that this diminution should not be attributed to the greater benignity of the disease during these months, as it did not seem to him that the number of light cases was very much greater than that of the graver ones. He attributes the cause of the difference to the better management of the service, which enabled him to isolate not only those with broncho-pneumonia, but also all children suspected of pulmonary affections.
With regard to the general symptoms of serum therapy, they may be early or late. Sometimes, although rarely, the author has observed, during the first few hours following the injections, transitory symptoms of general reaction, of which the only outward manifestation was an elevation of temperature, which sometimes rose to 102° F., but this lasted only a few hours, without any morbid or alarming symptoms.

More important, says M. Moisard, are the cutaneous manifestations following these injections. They appear early or late, and may be accompanied by general symptoms, and in some cases, by arthropathy sufficiently intense and lasting to simulate an attack of subacute articular rheumatism. Out of thirty-three cases, the writer had observed in fourteen urticaria, in nine erythema scarlatiniforme, in nine erythema polymorphum, and in one purpura. Urticaria was the most frequently observed by the author. It appeared at different times; sometimes, although rarely, several hours after the injection, sometimes two or three days, or even from ten to fifteen days after. It was more or less generalized and was not ordinarily accompanied by fever or general symptoms, and very little uneasiness or insomnia existed. This, says M. Moisard, is the least serious eruption due to the serum, but it may produce rather intense general symptoms. Quite different is the erythema polymorphum which was observed in the other cases. If, he says, in certain cases it appears without any general manifestation, with only its classic characteristics, in other cases its appearance is accompanied by more striking manifestations, and by general symptoms sufficiently intense to alarm any one not forewarned.

M. Moisard advocates the preventive injections, which have given, in his hands, such excellent results. At the Trousseau not one of the children who had been thus protected and left in contact with those suffering from the disease had taken it.

With regard to the accidents due to serum therapy, M. Moisard remarks that this method has a few disadvantages that are of slight importance and do not detract in the least from the value of M. Roux's and M. Behring's discovery, but he thinks it is well to know them. With regard to the local punctures, the accidents are exceptional. After six hundred injections made during the months of October and November, only one abscess had been observed. The child had received five injections, and the last one had been followed by the abscess, which had healed rapidly after incision. Rigorous asepsis of the skin and of the instruments explains the rarity of these local accidents among children, many of whom had received as much as 120 c.c. of the serum during the course of the disease. Aside from this, the author had observed only a slight sensitiveness, which generally persisted for twenty-four hours, and a transitory erythema around the inoculated spot. The general accidents, without being very frequent, are, however, sufficiently marked, and they indicate very clearly a true toxic action of the serum. The serum taken from certain horses has evidently, says M. Moisard, a more marked toxic action than that taken from others.

In an article on the same subject, published in the Lyon medical for December 16th, M. Rabot, physician to the Charité, gives an account of forty-seven cases that have come under his observation. Twelve of the children had laryngeal stenosis and were treated with the serum; one had been cured by this method alone, the others having been subjected to intubation. In five other cases the author had not been able to employ the serum, and only one patient had recovered. The thirty remaining patients had angina and croup, and the serum was used with the same results. Only sixteen out of the forty-seven died, making the mortality thirty-four per cent. The author considers this a brilliant result, as formerly it had not been far from fifty per cent., which was the mortality in 1893. This, in a service which is capable of treating five hundred patients in a year, is, he says, a result not to be disdained. The direct cause of death in his patients was uremia. Fourteen of them died during convalescence; one was brought to the hospital in a dying condition with paralysis of the pneumogastric nerve, and one died on the eighth day. Those who curbed died from pseudo-membranous bronchitis, three with broncho-pneumonia, and another with convulsive uremia. Those who recovered had had paralysis of the velum of the palate and albuminuria. In one case urticaria set in eight days after two injections of the serum. The method of treatment was by the employment of serum, the suppression of carbolic-acid spraying, which was replaced by salt water, ice, and lavage with a solution of salicylic acid; the use of slices of lemon peel was continued. No alcohol was given.

With regard to the preventive treatment, the author cites the following case: A child at the Sainte-Jeanne had a very serious attack of diphtheria, and one of the sisters, who was accustomed to nursing such cases, isolated the child and made a culture which was distinctly diphtheritic. The author, who was very much concerned at the appearance of such a malignant case in the general service, immediately administered an injection of serum to each child, and not one of them took the disease.

**The Ohio Pure-Food Law and "Vin Mariani."**—It is probably known to many of our readers that the zeal with which the law has been administered had among its recent results the arrest of a well-known Cincinnati druggist on the charge of having violated the pure-food law by selling Mariani's wine of coca, commonly known as "Vin Mariani." The Pure-Food Commission's chemist, Professor Charles T. P. Fenelon, held that the preparation was "not up to the standard within the meaning of the law." The law says: "An article shall be deemed to be adulterated within the meaning of this act: (1) If, when sold under or by a name recognized in the United States Pharmacopeia, it differs from the standard of strength, quality, or purity laid down therein. (2) If, when sold under or by a name not recognized in the United States Pharmacopeia, but which is found in some other pharmacopia or other standard work on materia medica, it differs materially from the standard of strength, quality, or purity laid down in such work. (3) If its strength, quality, or purity falls below the prescribed standard under which it is sold."

The commission's procedure, hasty and summary as it seems to have been in this instance, attracted wide attention by reason of the copious references made to it in the newspapers and on account of the great esteem in which the preparation had been held for many years. Consequently M. Mariani and his associates and representatives in business suffered an injustice —unintentional, no doubt, so far as the commission and its chemist were concerned, as is shown by the fact that Professor Fenelon has since acknowledged formally that an error was committed.

**A Proposed Memorial of the late M. Charcot.**—The pupils and former associates of Charcot in Paris and throughout France are engaged in raising a fund for the erection of a bronze statue of him in the Salpêtrière. This movement is now receiving cordial and material support in Germany, in England, and in Italy. It has therefore seemed desirable to the neurological societies of New York and Philadelphia that the profession in America join in this testimonial as an evidence of the eminent services of Charcot in neurology and in medicine. For this purpose the undersigned have been appointed a committee to bring the matter to the attention of the profession and to receive contributions, which will be duly acknowledged and forwarded to the central committee in Paris. It is request-
ed that all who desire to contribute to the success of this undertak- 
ing send their subscriptions to the members of the commit- 
etee nearest to them or directly to the treasurer; Dr. C. A. Her- 
ter, 819 Madison Avenue, New York, before the first day of 
February, 1895.

Ether and Albuminuria. The Nouveau Montpellier medical for December 15th contains a review of an article on this subject, by Dr. Barenfeld, which was published in the Münchener medizinische Wochenschrift. The writer remarks that, if etherization has still determined opponents, it is because the careful study of this method of anesthesia has often been somewhat neglected, and because, on account of some real inconveniences of the method, too much stress has been laid on observations of little value.

Certain American surgeons have maintained that ether exercizes an unfavorable action on the kidneys, but Barenfeld's researches go to show that this opinion is not very well founded. In order to determine the alleged relation of cause and effect between etherization and albuminuria, Barenfeld analyzed the urine of some persons who had been operated on, before and twenty-four hours after the operation. Out of a hundred and fifty cases albumin was found after the operation in four only, in two of which the patients had shown signs of albuminuria before the operation; moreover, in these two cases the quantity of albumin had not increased under the influence of the ether. With regard to the two cases where albumin did not manifest itself until after the operation, one of the patients had been subjected to laparotomy for intestinal occlusion, after having been for three days in a condition of extreme prostration and died on the day of the operation. The other one had been operated on for inguinal hernia by Kocher's method, and after the operation considerable albuminuria appeared and persisted, although gradually diminishing, for four days. It was, on the whole, says the writer, the only case out of the one hundred and fifty of true nephritis due to etherization.

The author reports, among others, a very interesting case of nephrectomy for left nephritis in a child of three years, who had borne the ether very well. There had been no vomiting, and after the operation not even a trace of albumin had been found in the urine.

Laboratory Teaching of Large Classes. To the discussion of this subject by the American Society of Naturalists in Baltimore, on Friday, December 28th, Professor B. G. Wilder, of Cornell University (unable to attend on account of the meet-
Original Communications.

THE USES AND ABUSES OF ANIMAL EXTRACTS AS MEDICINES.*

By HENRY HUN, M.D.,
PROFESSOR OF DISEASES OF THE NERVOUS SYSTEM IN THE ALBANY MEDICAL COLLEGE.

It was with much pleasure that I accepted the invitation, so kindly extended to me by your president, Dr. Stover, to read a paper before the Amsterdam Medical Society, and I devoted not a little time to considering various medical topics which might be made the subject of the paper. Finally it seemed to me that a discussion of The Uses and Abuses of Animal Extracts as Medicines might prove of interest and profit to us all, inasmuch as it is a subject which has attracted much attention during the past year or two, and seems destined to be the central point of therapeutic investigation in the immediate future.

A great variety of these animal extracts have already been tried in medical practice and the subject is so large that we can treat it only in outline. We will commence with a consideration of those extracts which seem to have been introduced in accordance with the old popular saying that "it takes a part to make a part." It is a very old form of treatment. It is stated in Pliny that among the Greeks and Romans in cases of impotence the semen or testicles of asses were swallowed. Galen's preparations of castor and musk have been used during centuries, and from his time down to the present day numerous examples can be found in the history of medicine of this kind of therapeutics. A few years ago Babes, in Bucharest, and Constantin Paul, in Paris, revived this form of treatment, and it has been exploited in this country with great zeal, not so much so by the physicians as by a stock company in Washington; and in many of the daily papers we can read the advertisement of "cerebrine" (extract of the brain), "medulline" (extract of the spinal cord), "cardine" (extract of the heart), "museuline" (extract of the muscle), etc., made according to the formula of Dr. William A. Hammond. For my part, I must confess that, eager as I am to try anything which may benefit my patients, I have no personal experience with these extracts. Among the reports of their action that I have read, I have not found one that seemed to offer me a probability of success; while Stockwell has disproved, by careful experiments, Hammond's views in regard to the action of cerebrine.

Practically, then, I can find no support for this plan of treatment, and theoretically it seems to me to be the most arrant nonsense. There is not only no reason to believe that the tissues are built up by the same tissues taken into the body in food, but we know the contrary. A baby may take nothing but milk, yet nourishes from it brain tissue and heart muscle. When it is an older child, or an adult, it takes more varied diet, but it practically never eats brains or hearts. As far as we know anything of animal chemistry the proper food for the nerve cell or the heart is the blood serum, which does not contain cerebrine or cardine. It is in the breaking up of the complex, unstable molecules in the blood serum and the consequent formation of simpler and more stable molecules that nerve force is produced. Cerebrine and cardine are not definite chemical compounds and, as far as they represent at all the chemical constituents of the brain or the heart at any one instant of time, consist as much of waste products, the results of cerebral or cardiac action, as of the nutritive constituents of the blood serum which may maintain such action. To suppose that a sclerosis of the posterior columns of the spinal cord can be made to disappear in some mysterious way by the administration of an extract of the nervous tissue is to give up all the knowledge of the chemical processes within the body so laboriously obtained by medical science, to return to the deepest mysticism in medicine, and to bring the healing art into disrepute. It seems to me that the attempt to cure a diseased organ by supplying a healthy one in the food has no support either in theory or in practice and is one of the chief abuses of animal extracts.

Somewhat allied to the extracts just considered are extracts of tissues which are supposed to possess especially strong chemical or vital (?) force, such as the spermatic fluid, or extract from the testicles, and nuclein derived from the nuclei of cells. It is conceivable that these highly potent chemical substances might, when injected into the body, increase the activity of the tissues generally. The spermatic fluid has, as we well know, the power of starting a wonderful series of activities by which a new life is generated, a new being produced. Furthermore, the removal of the testicles of an animal produces a decided alteration in its appearance and character which can only be regarded as a deterioration. In this case it would not seem impossible that some of the secretion of the testicles was absorbed into the system normally and affected the general nutrition of the body. There would seem, then, to be some reason for thinking that the extract of testicles injected into the system might have some effect in improving the nutrition generally.

This possibility, taken in connection with the distinguished name of the discoverer and advocate of this treatment, Brown-Séquard, secured from the outset a widespread adoption of it. This treatment rolled in a great wave over the whole world. It was tried everywhere, and many an old man died of septic infection from the injections; but good results from it were few and of a very uncertain nature, and in a few months the craze about it was a thing of the past. Doubtless in many cases the extract was improperly prepared and improperly used, but even the results obtained by Brown-Séquard himself, or by Pölzl with injections of his "spermin" (which he finds in a great many of the internal organs besides the testicles), are most indefinite and unsatisfactory and are expressed most unscientifically, as far as I have seen them reported; while

* Read before the Amsterdam, N. Y., Medical Society, December 4, 1894.
† Medical News, Aug. 26, 1893, p. 231.
the reports of failures with this method of treatment are very numerous.*

It is not impossible that nuclein taken into the body might exercise a general tonic effect upon it. It is the most active principle of the cells which compose the various tissues of the body. Vaughan has devoted much study to the preparation and therapeutic action of nuclein. It has been proved by him to have a germicidal action on many bacteria,† and he has offered some evidence that it is of therapeutic value.‡ It can be obtained from the spleen, the thyroid gland, the testicles, and other animal tissues, but, according to Vaughan, it is most conveniently extracted from a pure culture of yeast by a dilute solution of potassium hydrate. From this solution other proteid bodies are first removed by precipitation with dilute acetic acid. Then nucleinic acid is precipitated by the addition of hydrochloric acid and alcohol. It is purified by repeated washings and precipitations. Such a preparation is now made and sold by Parke, Davis, & Co. At the present time it has not been tried long enough for any correct judgment to be pronounced as to its value, but it is certainly worthy of a careful and extended therapeutic trial.

Turning now from these extracts, which have either no therapeutic value at all or whose value is yet to be proved, we shall consider other extracts whose value is so striking that it can be proved with the greatest ease. There are a great many secretory glands in the human body, and each one of these probably supplies a secretion which fulfills a more or less useful purpose. When any secretory gland fails to do its work it may be of the highest importance to supply to the body from without this lacking secretion. Such a procedure is perfectly rational, and for many years it has been an established practice to give in cases of difficult digestion an extract from the mucous membrane of the stomach—"pepsin"—or an extract from the pancreatic gland—"pancreatin"—or, more rarely, dried ox bile.‡ The widespread use of pepsin and pancreatin proves that in many cases they are of value. Doubtless their employment has been much abused. There is nothing curative in them. In cases of gastric catarrh or of abnormal gastric secretion we can bring about a more rapid and more pronounced cure by the bitter tonics, the alkalies, and by other methods of treatment. Nevertheless, in many cases pepsin and pancreatin are of distinct value, and when the normal gastric secretion is temporarily or permanently absent, the temporary or permanent use of these extracts is strongly indicated, not to bring about a cure, but to supply a secretion which is absent and thus to maintain a digestion which would otherwise be imperfect or impossible. The use of pepsin and pancreatin is well known and firmly established, so that we may leave this portion of our subject with more extended discussion and hasten on to an even more striking instance of the use of animal extracts.

Some ductless glands, which are therefore not secretory glands in the ordinary sense of the word, have the duty through their products entering the blood, probably by way of the lymphatics, of modifying the chemical character of the blood and thereby of exercising an influence on the nutrition of the entire body. Among such glands the thyroid occupies a prominent position. Concerning the functions of the thyroid gland nothing was definitely known fifteen years ago. We now know, however, that when the thyroid is completely removed by a surgical operation, or is congenitally absent, or is atrophied, or its function is destroyed by disease, a very curious set of nutritive changes take place throughout the body, which you may find described at length in a paper published by me in 1888,* and which make up a clinical picture of a disease called "myxedema," or "cachexia strumipriva," or, when congenital, "cretinism." Now, when the thyroid gland of a healthy animal, such, for instance, as that of a sheep, whether in the form of a glycerin extract or of slices slightly cooked, or in the more convenient and more permanent form of the powdered desiccated gland, is given to a patient suffering from myxedema, all the symptoms of the disease disappear with a certainty which is rare in medical practice, and is not found to be the case in any of the extracts previously mentioned. The reports of this form of treatment show a wonderful uniformity of favorable results. I reported in the Albany Medical Annals of January, 1894, two cases of myxedema cured by the administration of the powdered gland. Of course, in such cases it is necessary to supply the thyroid gland to the system at intervals of a year, more or less, throughout life.

While the thyroid gland is being administered most patients exhibit a certain degree of exhilaration, so much so as to suggest the idea that the gland might be of use in melancholia. In one case of circular insanity, by administering the thyroid gland I transformed the case almost instantly from the stage of melancholia into that of mania. I then wrote to a friend in one of the State hospitals for the insane requesting him to give it a trial in cases of melancholia. The results which he obtained were not, however, very definite; but in a recent number of the Lancet Dr. Macphail and Dr. Bruce† reported a series of cases of various forms of insanity treated with large doses of thyroid extract in which the results were both surprising and gratifying.

Another effect of the administration of the thyroid gland is, in the majority of cases, a rapid and large reduction in weight, so much so that it has been frequently used with this aim alone in view. I have tried it now in some half a dozen cases of obesity, and know of no more potent drug for this purpose. It must, however, be given with caution, as sudden death from cardiac paralysis has been known to follow its administration, and I have seen it disturb the heart's action very much in several cases. Lately it has been claimed that the thyroid extract will cause the

---

† Lancet, October 13, 1894, p. 846.
disappearance of a goitre. It does not seem easy to reconcile this statement with our present ideas in regard to the physiological action of the thyroïd secretion, and the claim needs confirmation by other observers before it can be accepted. I believe, however, that the thyroïd extract will be found to possess other therapeutic uses besides those already discovered.† It is probable that in time the functions of other ductless glands besides the thyroïd will be discovered, and that diseases dependent upon the failure of action of these glands will be cured by the administration of their extracts.

Let us now turn from the glands to analogous bodies. We know that the marrow of the bones is an organ in which the red blood-corpuscles are formed. Pernicious anaemia and leucocytæmia are two diseases which terminate fatally, and which present as the principal symptom a great deficiency in red corpuscles. During the past few months cases have been reported of complete and rapid cure of both of these diseases by feeding with bone marrow. Doubtless some of these cases have been reported too soon, and the improvement may not be permanent, and much further proof is needed before the curative effect of bone marrow in these diseases can be regarded as established; but the outlook is bright that these two diseases, hitherto regarded as absolutely fatal, can be cured by this simple means. If the bone marrow is found by experience to possess therapeutic value, it will probably prove of use in all cases of anaemia. In chlorosis, where a deficiency of haemoglobin rather than a deficiency of corpuscles is the fault, the preparations of iron will probably maintain their supremacy as curative agents. Nevertheless, I have recently obtained very rapid and decided improvement in a case of chlorosis to which I administered bone marrow, although Bland’s iron pills had been taken for a long time previously without decided effect.

We have now considered the principal animal extracts which have been obtained from the healthy animal and which have been employed in the treatment of diseases. There remains for us to consider those animal extracts which can be obtained only from the diseased body. This subject is only in its infancy, but it has already given results which seem destined to revolutionize the practice of medicine. As the result of a large number of experiments on animals, it seems now to be pretty definitely settled that pathogenic bacteria, introduced into the body, disturb the system locally by their growth and generally by certain poisons (toxalbumins), which are produced by their growth. Usually the general symptoms are much more the severe, and are those which cause the fatal termination, if death occurs. It also seems to be pretty definitely settled that in the germ diseases there is formed in the blood serum a chemical compound, which not only neutralizes and destroys the toxalbumin, but, when injected in sufficient quantities into a healthy animal or man, renders him immune for the corresponding disease, and in larger quantities is even capable of curing an animal or man sick with the disease.

The last of the animal extracts which we have to consider are these antitoxines, which are prepared in the following manner: A large flask of nutritive bouillon is inoculated with a little of the pure culture of diphtheria bacilli, and these are allowed to grow at a suitable temperature. After about a month the bacilli are killed by adding half of one per cent. of carabolic acid. The dead bacilli fall to the bottom of the flask, and the fluid above them contains the diphtheria poison. A small quantity of this diphtheria poison, less than the dose which is found certainly to kill the animal within three or four days, or else this fatal dose mixed with some trichloride of iodine, which acts as a kind of antidote to the poison, is injected into an animal. The animal reacts to the injection by fever, by edematous swelling at the point of injection, and, what is most important, with the production of antitoxine. After the animal has fully recovered from the first injection, a second is made containing a little more of the poison, or a little less of the trichloride of iodine, and after the animal has entirely recovered from the second injection a third is made. With each injection the amount of the specific antitoxine in the blood is increased, and the injections are continued until the blood contains the required amount of this specific body.

From time to time the blood of the animal is tested to see how strong the antitoxine in the serum is. Ten times the minimum dose, sufficient to cause the death of the animal in three or four days, is mixed in a reagent glass with a varying quantity of the blood serum, and, after thorough mixture, it is injected into the animal; and that amount of blood serum which is sufficient to prevent the animal from showing any symptoms of disease is the amount which is necessary to neutralize the tenfold minimum dose of the diphtheria poison. In order to get some way to measure the antitoxine in the blood, a so-called normal serum is taken as a standard. Of this normal serum, one tenth of a gramme is sufficient to neutralize completely a tenfold amount of the minimum dose of the poison, and one cubic centimetre of this “normal serum” is said to contain one “immunity unit.”

It is found, in order to cure diphtheria in children, that a serum containing five hundred immunity units is needed—that is, ten cubic centimetres of a fiftyfold normal serum, or five cubic centimetres of a hundredfold normal serum, must be used. When the blood of an animal, subjected to increasing injections of the diphtheria poison, is found by experiment to contain the requisite amount of antitoxine, the animal is bled largely. The blood is received in sterilized vessels and put into an ice chest until it has coagulated. The clear serum separated from the clot is mixed with half of one per cent. of carabolic acid in order to keep it, and is then ready to be used for the cure of diphtheria.

The injection of this serum is perfectly harmless; it can be injected in large doses, and exercises no influence on the

* Bruns. Deutsche medizinische Wochenschrift, 1891, No. 41, p. 785.
+ Much of what follows is taken with modifications from an article by Kossel, Deutsche medizinische Wochenschrift, October 25, 1894, p. 823.
temperature, or on the kidneys, or on the heart. There have been no unfavorable symptoms observed from its use. The effect of the injection in cases of diphtheria is most marked on the general symptoms. A few hours after the injection the temperature begins to fall, the pulse also falls, and in the course of twenty-four hours in recent cases the temperature and pulse return to normal. The local trouble in the throat is also decidedly influenced, but not so rapidly. The action of the antitoxine manifests itself locally by a more rapid exfoliation of the membrane. Perhaps the next day after the injection more membrane will be seen in the throat than at the time of the injection, but the membrane has only appeared on parts which the day before were reddened and swollen and had already been invaded by the disease. Twenty-four hours later it will be evident that the process in the throat has not extended, and that the membrane is beginning everywhere to be cast off. The injection is best made at the lower part of the axilla, where relatively large amounts of fluid can be injected and readily absorbed, and the injection should be made with an antiseptic and sterilized syringe. The antitoxine is made under the direction of Behring and Ehrlich, and is sold in three varieties of bottles. The entire contents of each bottle are to be injected at one time, and each one possesses a different strength.

No. 1 contains six hundred immunity units, and suffices for recent cases in children in the first or second day of the disease.

No. 2 contains a thousand immunity units, and is used in more severe cases, or in cases of more than two days' standing, or in those in which the larynx is involved.

No. 3 contains from fifteen to sixteen hundred immunity units, and is used in adults or in very severe cases in children.

The other members of the family can be made "immune" during a month or two by injecting a quarter of the amount of No. 1. It is better to inject the full dose needed in any case at one time rather than to divide it into two doses.

Kossel states that among the children, suffering from all forms of diphtheria, brought to be treated with this serum at the Institute for Infectious Diseases in Berlin, the mortality has been reduced to sixteen per cent. All the children that were treated on the first or second day of the disease recovered, so invariably so that Kossel is now convinced that it is possible to cure every recent case of diphtheria by employing a suitable amount of antitoxine. Katz, in one of the children's hospitals in Berlin, among a hundred and fifty cases treated in this way, found a mortality of sixteen per cent. Roux, in Paris, reports that of four hundred and forty-eight children treated with antitoxine, there was a mortality of twenty-four and a half per cent., while at the same time five hundred and twenty cases of diphtheria treated by other means showed a mortality of sixty per cent. In cases of simple diphtheria, not requiring tracheotomy, the mortality was thirty-four per cent., but among similar cases treated with antitoxine the mortality was twelve per cent.

A great many other cases have been reported in smaller numbers by a large number of observers and the results have been most favorable, so that this method of treatment seems to be a great advance on any other. Of course, it has not been tried long enough yet for us to get a correct estimate of its value; but it is probable that with more extended experience in the use of antitoxine, with better methods in its preparation, we will be able to get a stronger antitoxine and produce better results than even those which have already been obtained, so that this form of treatment, as far as we can judge, has a most brilliant future before it. Experiments have been made with the aim of producing the antitoxine in other ways, either from blood serum or entirely independent of this fluid, but as yet they have not been successful.

Tetanus is a disease which has been treated by its antitoxine in exactly the same way as diphtheria. But tetanus is comparatively rare, and when the muscular spasms (the diagnostic symptoms) are observed, the disease has already been in existence a considerable time, and even at that late stage it is in most cases difficult to get the antitoxine promptly, so that the statistics at present in regard to this method of treatment are conflicting, and no true estimate of its value can yet be formed.

If the antitoxine treatment of diphtheria proves successful, there is no apparent reason why other infectious diseases can not be cured in the same way, and the experiments which have already been made, not only in cases of tetanus, but in cases of pneumonia and typhoid fever as well, although as yet few and not convincing, give promise of a bright future in this department of therapeutics.

The attempt to convert the toxin of a germ into its antitoxine, or by the application of a suitable degree of heat to the toxalbumin solution to destroy the toxin and to leave the antitoxine intact, and then by injecting this altered product of bacterial growth to cure the corresponding disease, although closely allied to our subject, yet, strictly speaking, does not form a part of it, for it is not an animal extract.

If we summarize the conclusions arrived at in our short consideration of the animal extracts we may say: 1. That the attempt to cure a diseased organ by supplying a healthy one in the food has no support either in theory or in practice. Such therapeutics is an abuse of the animal extracts.

2. That the administration of extract of the testicles has a slight support in theory, but has no sufficient support in practice, and must be regarded as an abuse of animal extracts.

3. That nuclein has not been sufficiently tried to allow us to form any estimate of its value.

4. That the digestive ferments have a distinct but

* The antitoxine of diphtheria is also made under the directions of Aronson and sold by E. Schering.
† Deutsche medicinische Wochenschrift, Oct. 25, 1894, p. 823.
‡ Berliner klinische Wochenschrift, July 16, 1894.
§ British Medical Journal, 1894, No. 1765, p. 931.

limited therapeutic value. Their administration is in many cases useful, but often degenerates into an abuse.

5. That the extract of the thyroid gland is of the greatest value in myxœdema and cretinism, and has also a decided value in the reduction of obesity, and has probably some value in the treatment of insanity. It must certainly be classed among the useful extracts.

6. That bone marrow will probably be found to be of value in cases of anaemia and leukœœmythia and perhaps in cases of chlorosis also. It is as yet too early to decide as to its uses and abuses.

7. That in the antitoxine extracted from the blood serum, or in the "blood-serum therapeutics," as it is often called, we have decided evidence that we possess an agent of great value in the treatment of diphtheria, and we have every reason to hope that it will prove of value in the treatment of all forms of the infectious diseases. It is a line of treatment that can hardly be abused and seems to have a wide field of great usefulness.

We have thus completed, although in a very fragmentary manner, our general survey of the field of "animal-extract therapeutics." It constitutes, I believe, the most remarkable advance that therapeutics has ever made. Hitherto it has been based almost entirely on empiricism, and the wonderful achievements of the various medical sciences have either left therapeutics unchanged, or have merely stripped from it some of its supposed powers. It has been the opiumbrium of medicine, and because it has had no definite basis charlatans and cure-alls have multiplied. But in the department of animal extracts there are now substantial theories and many correlated scientific facts supporting the therapeutic measures. For the first time the therapeutic art stands on a firm scientific basis, and has before it the possibility of developing and growing in a regular and orderly manner. Already under these new and better conditions it has achieved results that were before impossible, and, what is more important, it is in the proper scientific path; it has adopted scientific methods; it is able to reason, to predict, to grow, and it seems certainly to have before it a brilliant future, the limits of which no one may venture to predict.

THE DIFFERENTIAL DIAGNOSIS OF TRAUMATIC INTRACRANIAL LESIONS.

By CHARLES PHELPS, M.D.,
SURGEON TO BELLEVUE AND St. VINCENT’S HOSPITALS; CONSULTING SURGEON TO GOVERNOR HOSPITAL.

(Concluded from page 44.)

Case X.—Male, aged thirty-one years; struck by a brick which had fallen five stories; no other immediate general symptom but unconsciousness. A compound depressed fracture crossed the median line at the vertex. Second day: there was accurate memory of events up to time of injury, no recollection of anything that occurred afterward. Third day: fragments of depressed bone were removed, leaving an opening in the skull two inches by an inch and a half in its diameters; no lesion of dura or of the sinuses. Temperature on admission 104-4°, at time of operation 100°, subsequently 99°+. Pulse and respiration at all times normal.

Case XI.—Male, aged thirty-two years; fell from his truck and struck the pavement upon the back of his head; partial loss of consciousness and delirium, which continued for three days. Fourth day: limited power of comprehension, no response to questions asked, attention fixed only with difficulty, opoctic headache which was not increased by pressure or percussion, and somnolence. At the end of four weeks the patient sat up, but walked with difficulty on account of imperfect muscular co-ordination in both legs; patellar reflexes normal; mind clear but slow in action, which he himself noted; vertigo, which was not of previous occurrence; opoctic headache relieved. Dr. P. A. Callan discovered upon ocular examination a neuritis, more advanced upon the right side than upon the left, and a paralysis of the ocular muscles. Temperature on admission was 99°, rose to 100-4° on the same day, was from 99° to 101° till the sixth day, 98-5° to 99°+ till the twenty-first day, and afterward continuously normal. The pulse was normal. The respiration was 12 for three days, 16 to 18 for six days, 8 to 12 for thirteen days, and afterward 16 to 20.

Case XII.—Male, aged thirty-five years; fell one story; brief unconsciousness followed at once by delirium; extensive lacerated wound in left parietal region; hemorraghe from left ear caused by wounds of external meatus. Temperature on admission, 104°; pulse, 80; respiration, 18. Delirium continued three weeks, gradually diminishing in degree and constancy; no subsequent recollection of the manner of injury. Loss of urinary control lasted one week; no headache at any time, and no later symptoms. Patient recognized his family and surroundings after three or four days.

Case XIII.—Female, aged five years; struck by a falling box which seemed to have crushed her head laterally against the floor. Still unconscious at time of admission, but very sensitive to external irritations; slight twitching of right side of the face, slight epistaxis, slightly accelerated respiration, slow and irregular pulse; temperature, 95°; pupils sometimes normal, sometimes widely dilated, with conjugate deviation which was sometimes upward and sometimes to the left; vomiting soon after reception of the injury; haematoma over entire vertex, and contusion of both eyes. Incision disclosed fissures on either side of the calvarium; one extended from the left temporal fossa posteriorly across the vertex to the right occipital region, and anteriorly into the anterior fossa; another, apparently beginning in the right anterior fossa, crossed the right parietal bone and terminated in the first. The bone was depressed posteriorly and the fissure open; after elevation and removal of some small fragments considerable epidural hemorrhage was apparent. Consciousness was fully restored within twenty-four hours, and was marked by restlessness and delirium, which continued for two or three days, after which the mental condition was normal. On the fifth day paraplegia occurred, which was almost complete from the first, and absolute on the next day, with partial anæsthesia; no paralysis of the bladder or rectum. The paraplegic condition began to improve at the end of a week's time, but very slowly; a few steps could be taken without assistance six weeks later. The temperature soon after admission rose from 93° to 98-5°, on the next day to 100-2°, and after the third day varied from 98-4° to 99-8°; usually normal in the morning. The respiration was accelerated for the first ten days, and the pulse frequent for three days.

Case XIV.—Female, aged thirty years; was thrown from a wagon while driving, striking the back of her head upon an asphalt pavement; shock, loss of consciousness for twenty minutes, and severe vomiting, which persisted during the day; temperature, 106°; not taken afterward; haematoma in right occipital region, and ecchymosis behind the right ear, followed
by severe localized pain in the right side of the head posteriorly. The later symptoms were a numbed feeling in the right ear, with diminished hearing and blunted perceptions of smell and taste which had been noted from the time of the accident. The disorders of hearing did not continue after the fourth week, but the senses of taste and smell have been permanently impaired.

Case XV.—Male, aged thirty-three years, struck on the head with a hammer and was momentarily unconscious, after which he walked to the hospital. Compound depressed fracture of the mid-vertex; both pupils dilated; left radial pulse markedly fuller and stronger than the right till after operation, five days later; no other general symptoms. Depressed fragments of bone were removed, leaving an opening in the skull an inch and a half by one inch in its diameters; hemorrhage from a large wound of the longitudinal sinus controlled by gauze packing. Pulse and respiration became normal on the following day, and radial pulsations symmetrical on the third day. Elevation of temperature was maintained by a slough and inflammatory conditions produced by an accidental burn. Temperature on admission was 99.2°, rose in a few hours to 101.4°, and after the operation to 102.5°; pulse and respiration, normal at first, were subsequently only moderately accelerated.

Case XVI.—Male, aged thirty years; fell twenty-five feet from a ship's deck to a raft alongside; consciousness lost for a few moments only; hematomata over right posterior parietal region; moderate contraction of the left pupil; right radial pulse fuller than the left; urine retained; complete paralysis of left lower extremity; nearly complete paralysis of the left arm; partial paralysis of the right upper extremity; anesthesia of the right side of the body below the third rib; hyperesthesia of the left lower extremity; great pain and tenderness in cervico-dorsal region, and evident fracture of the first dorsal spine; mental condition apparently normal. During the first week vomiting occurred at least once in each twenty-four hours, and pain in the frontal and in the upper dorsal region was constant and severe. The bilateral variation of the pulse was distinct till the fifth day. The paresis, hyperesthesia, and anesthesia, and the contraction of the left pupil persisted in greater or less degree for several months, and a paresis of the left lower extremity and the anesthetic and hyperesthetic conditions and the contracted pupil existed at the time of final discharge from the hospital.

An ophthalmic examination was made by Dr. Callan, and repeated at a later period, with negative result. The eye was retracted and a little less sensitive than the other, but there was no retinal change, and no loss of power in the ocular muscles.

There was no mental disturbance till the occurrence of nocturnal delirium and restlessness at the beginning of the third week. A few days later the nocturnal delirium ceased, but the restlessness at night increased, and delusions of a painful character began to occur, which occasioned the patient much distress. The first trouble which came to him was the fancied death of his wife, and when, a little later, he became convinced that this bereavement was imaginary, he was equally positive that another delusion, the death of his child, was real, and this new conceit possessed his mind for many weeks. He suffered acute mental anguish in each instance, which could have been scarce exceeded had these pure fancies been actual facts. The facial expression grew a little stupid, and an inclination to weep was manifested on ordinary occasions, equally when the amount of cutaneous hyperesthesia was tested, or when discourse turned upon his family afflictions, but speech was always coherent. At the end of the second month there was some improvement; the facial expression brightened, delusions were less constant and of a more trivial character, and the mental condition was less uniformly clouded. In the third month delusions altogether disappeared, and mental processes, though slow, were no longer distorted; he was enabled for the first time to recall the manner of his injury; vertigo, which had been an early symptom, still persisted.

The temperature on admission was 98.4°, rose during the day to 101.8°, and on the fifth day reached 103°. It was habitually high till late in the second month at some time in each twenty-four hours, not less than 101.9° to 102.5°, the diurnal variations being also considerable. The left axillary temperature was markedly higher than the right, usually five tenths of a degree or even more. The pulse was ordinarily from 80 to 90, occasionally 60 to 70, and rarely exceeded 100. The respiration during the first month was not often less than 30 and later ranged from 28 to 24.

The patient left the hospital seven months after admission. There was then no trace remaining of the cerebral injury beyond a little heaviness of manner and a little slowness of thought. The persistence of the spinal lesion was indicated by a stationary paresis of the lower extremity and by a continuance of the disorders of sensation which immediately followed the traumatism. The left eye was still retracted and insensitive and its pupil small.

Case XVII.—Male, aged thirty-six years; fell ten feet from a vessel to a raft alongside and then into the water; brief period of unconsciousness, profuse hemorrhage from left ear, slight epistaxis from left nostril, and hematomata in left mastoid region; single general convulsion in the ambulance followed by stertor; consciousness regained at time of admission; both pupils widely dilated; hemorrhage from the ear recurred during the night; urine retained; temperature, 98.8°. Frontal headache continued for several days, and on the third day there was transient photophobia with contracted pupils. The bladder and rectum were controlled. Dilatation of the pupils was perceptible till the end of the second week and of the right pupil even longer. The prominent symptoms were mental; nocturnal restlessness and delirium, and a rather stupid condition during the day, were succeeded in the second week by continued delirium of a mild type with delusions. In the third week active delirium ceased, though restlessness at night persisted; the facial expression was more intelligent and speech was coherent; there was perfect recollection of the manner in which the injury had been received, and also of a similar accident which had occurred on the same day and aboard the same ship (Case XVI, immediately preceding), but delusions were numerous and constant. At the beginning of the fourth week the patient was restless, excitable, talkative, and had again forgotten the manner and even fact of his injury. Ophthalmic examination was made by Dr. Callan with negative result. At the end of the fourth week delusions finally ceased, and when discharged from the hospital in the eighth week there were no symptoms remaining. The sense of smell was entirely lost.

The maximum temperature was on the fourteenth day, from 101° to 102.2°; the usual temperature was 99° till after the fourth week, and then varied from normal to 99°. The axillary temperatures were observed from the fourth to the eighth weeks; the left was habitually, but irregularly, higher than the right. The pulse and respiration presented no notable changes.

Case XVIII.—Female, aged seventeen years; fell from second-floor window; found in coma with profuse hemorrhage from left ear and some hemorrhage from the mouth; left side of face, eye, and parietal region much confused. Two hours later consciousness was partially restored and sensibility to external impressions recovered; hematemesis occurred, and at a later period, after subsidence of ephymosis of the lids, subconjunctival hemorrhage in the left eye was discovered; the
right pupil was dilated. Six hours after admission, temperature, 97.4°; pulse, 70; respiration, 38; lack of urinary control. The haemorrhage from the left ear continued for thirty-six hours, and was followed by a discharge of bloody serum. During the first three or four days the patient was at times noisy and restless and at times quiet. She then became rational and learned for the first time that she had met with an accident and was in a hospital; but she never knew, then or afterward, of her own recovery. At about the same time a protrusion of the left eye became marked, and it was discovered that vision was lost on that side. There were no additional symptoms. The temperature on the second day was 100°; pulse, 68; respiration, 18; and temperature afterward varied from 99° to 100°.

At the end of the fourth week ophthalmic examination was made by Dr. Callan. The right eye was in all respects normal. The left eye was on a slightly anterior plane to that of the right; its movements were unimpaired; there was a slight remaining trace of haemorrhage near the limbus cornææ; the pupil was moderately dilated and not responsive to direct rays of light, but acting consensually with the right; there was commencing atrophy of the optic nerve and total loss of vision. From the clinical history Dr. Callan was of opinion that a line of fracture had implicated the left optic foramen.

Case XIX.—Male, aged forty years; found in the street in an alcoholic condition; could walk with assistance; profuse haemorrhage from left ear; slight edema of scalp in left occipital region; no general symptoms. The recollection of having been brought to the hospital and of previous wanderings, but not of the manner of injury, returned with sobriety. Ecchymosis of both lids of right eye appeared on the following day; vertigo and occipital headache and some pain behind the left ear existed for ten days. Temperature on admission, 98.4°; rose to 101° in the course of eighteen hours, and was afterward 99° to 100°+ during the three weeks the patient remained under observation. The axillary temperatures were usually symmetrical, and when any difference was noted it was higher on the left side. The pulse more frequently exceeded 90 or 100 than is usual in similar cases. The respiration was normal.

Case XX.—Male, aged nine years; fell ten feet from a dump into a scow; consciousness lost for fifteen minutes; no external injury; temperature, 99.2°; pulse, 67; respiration, 28. Third to fifth days, right radial pulse fuller and stronger than the left; somnolence till seventh day, and recurrence on the tenth and eleventh days with a condition of mental indifference; occipital pain continued at intervals during ten days. The temperature five hours after admission was 100°, in twelve hours was 101°, and did not exceed that degree; it was 99°+ to 100°+ for fourteen days, with an occasional decline to normal for a single observation or for a few hours. The axillary temperatures were observed four times daily, and the left was habitually six tenths of a degree or more higher than the right, and sometimes the difference was as great as a degree and eight tenths; they were occasionally symmetrical, but in sixty-eight observations the right was never the higher. The pulse was usually 52 to 84, and more frequently approximated the lower figure. The respiration was from 18 to 28.

Case XXI.—Male, aged fifty years; fell twelve to fifteen feet from a loft and struck upon the back of his head, six hours previous to admission; unconscious fifteen minutes; contusion of the vertex in the median line; wound in right occipito mastoid region; haemorrhage from right ear; delirium from time consciousness was restored, often requiring mechanical restraint; dilated pupils, and right radial pulse fuller and stronger than the left; the urine was retained and the right hand and wrist were paralysed. There was marked splenosis—e.g., the patient said "tall that" for stop that, "guth Got" for good God, and "15 Avenue B" when asked his name. The difference in the fullness and strength of the radial pulses continued to be strongly marked at all times till death on the eighteenth day. The dilatation of the pupils, which remained sensitive till the fourteenth day, was also permanent. Delirium persisted, and speech was infrequent and unintelligible till the close of the first week; the mental condition then became brighter and speech distinct and coherent, but delusions were constant and the patient was at no time able to recognize his family or friends. There were frequent alternations of restlessness and excitability with somnolence or lethargy, but no cession of delirium, delusions, and more or less incoherent and unintelligible speech, till final unconsciousness, which occurred three days before death. Sensitivity to external irritations was marked throughout this later stage. The control of urine and feces was permanently lost during the first few days. The paresis of the right hand was much diminished during the first week. On the sixth day, and on the seventh, there was a short, severe convulsive attack, followed by a transient high temperature. These were succeeded on the morning of the eleventh day by a general convulsion, which was at first confined to the upper extremities, and continued twenty minutes; the right arm was less rigid than the left. Another attack in the afternoon of the same day, of twenty-five minutes' duration, began with a twitching of the facial muscles, and was extended to the trunk; all the extremities remained rigid; the face was of a natural color, though subsequently much flushed, but the hands were blue. The morning convulsion was followed by prolonged unconsciousness, that of the afternoon by an apparently natural sleep after a short interval in which the mind was unusually clear and alert. There was another very brief general convulsion five days later. Posterior cerebral muscular rigidity existed from the ninth to the fourteenth days. The temperature on admission was 101.8°, and varied from 100°+ to 101°+ till the fourth day, when, without other change in symptoms, it rose to 104°; and in the twelve hours following declined to 101°+, and was continuous at about that degree till the tenth day, except at the time of the first and second convulsive attacks, when it rose for a short time to 106° and 106° 6°; on the morning of the tenth day it rose to 105°, again declined to 101°, and with the occurrence of the third and fourth paroxysms on the eleventh day it rose to 105°+; on the twelfth day it declined for a brief interval to normal, and was subsequently uniformly high, from 103° to 106°, and at death was 108°. In fifty-two observations the right axillary temperature was higher than the left in thirty-two, the left higher than the right in seven, and in thirteen the two were uniform; the variation was from two tenths of a degree to a degree and eight tenths. The pulse on admission was 112, and then for the first ten days, 65 to 100; never afterward below 120. The respiration on admission was 36, and after the first four days rarely below 32.

Case XXII.—Male, aged forty-two years; fell in the street, striking the back of his head; consciousness lost, but regained on the way to the hospital; mental condition stupid, but rational, becoming normal in a few hours; slight general headache; later, frontal pain, followed same day by a single general convulsion of five minutes' duration; head and eyes turned to the right; left side and extremities actively convulsed; right arm and leg motionless. On the third day there was transient posterior cerebral rigidity, and on the third and fourth days the left radial pulse was fuller and stronger than the right. During the first ten days the patient's condition was marked by stupor, occasional somnolence, slowness or refusal to answer when questioned, nocturnal delirium becoming continuous,
PHELPS: DIFFERENTIAL DIAGNOSIS OF INTRACRANIAL LESIONS. [N. Y. MED. JOUR.]

frontal pains, and contracted pupils. In the week following there were delusions, lack of facial and urinary control, increased somnolence and stupor, some mewing delirium, and pains in the back of the head and left extremities, succeeded by left paresis. After this time the patient occasionally indicated more intelligence when roused from his habitual stupor, and once conversed intelligently with his wife. The pupils remained contracted and insensitive to light, the urine and feces uncontroıld, the limbs drawn upward, and any disturbance of the left side of the body was resented. On the twenty-fifth, the last day of life, articulation was indistinct, deglutition difficult and death, preceded by restlessness and some brightening of the mental condition. The temperature on admission was 98°, rose to 103-2° on the third day, and was subsequently 99° to 100°+ till the last day, when it was 107-2°. The pulse on admission was 80, on the fifth day 42 to 58, and at other times 68 to 100. The respiration varied from 18 to 24. A few hours before death both pulse and respiration became frequent.

Case XXIII.—Male, aged thirty-eight years, admitted in an alcoholic condition without a history; profuse hemorrhage from the left ear. The patient never afterward remembered having been hurt. During the first week hearing was greatly impaired in both ears, and there was much mental confusion, with sensory aphasia and general loss of memory. General headache was severe and vertigo marked. The patient was enabled to recollect with great difficulty the place of his employment, and could only suggest his occupation as a waiter by using an imaginary corkscrew in dumb show. The right radial pulse on the second day was fuller and stronger than the left. In the second week hearing was quite restored in the right ear and was nearly recovered in the left. The mental condition became normal, and there were no further symptoms. The temperature on admission was 99-3°, and did not subsequently exceed 100°+. The left axillary temperature was two tenths of a degree higher than the right when there was a lack of symmetry. The pulse on admission was 80, and was only once above 100. The respiration was from 18 to 24.

Case XXIV.—Male, aged forty years; fell six feet into an area way; consciousness lost, and not restored at time of admission, but sensitiveness to external impressions retained; profuse hemorrhage from right ear; left radial pulse fuller and stronger than the right; pupils contracted, but responsive to light; right corneal reflex diminished; right side and right face paretic, and urine retained. The pupils became normal on the second day, and the radial pulses symmetrical on the third, with some signs of returning consciousness. Convulsive movements of the extremities occurred on the fourth day, and there was some dysphagia. The patient gave little evidence of intelligence till the end of the fourth week; he had no power of speech beyond the utterance of an occasional single word, and when his attention could be attracted, which was not often, replied only in inarticulate sounds; he rarely recognized his immediate family, and had no apparent comprehension of what was said to him. The right facial paralysis continued, with added ptosis of the left eye, and both pupils became dilated. His mind then became clearer, but intelligence was very limited; he articulated several words with moderate distinctness, and a little later used several short phrases with propriety; a little later still his attention could be momentarily fixed to comprehend and answer monosyllabically a simple question. An ophthalmic examination made by Dr. Callan disclosed no retinal changes. At the end of the sixth week he began to notice what went on about him, recognized his mother, and developed destructive tendencies. Early in the seventh week he first gave attention to the natural offices of the body, and his increasing range of words accentuated his aphasia. After the second month there was only a trace of facial paralysis, and no other paretic condition. He could dress himself, and went about the ward; he could remember, and could write, his name and address correctly, and seemed to readily understand such questions as were asked him, but replied in an endless tirade which was incoherent and largely made up of inarticulate sounds interspersed with recognizable words, and apparently as devoid of meaning to himself as to the listener. He was unable to write from dictation more than a few words before the written characters became incomprehensible, and he repeated words. He had no knowledge of his occupation, manner of injury, or local surroundings. He was discharged at the end of the third month, and had then upon cursory examination no symptoms of mental disorder remaining, except some hesitancy in collating words, and in long sentences a little confusion in expression. If an attempt was made, however, to engage him in a sustained conversation, his thoughts became more and more entangled; he talked rapidly and excitedly, and his words were inextricably jumbled together. On examination, four months later, his mental condition was that of dementia.

The temperature on admission was 98-4°, and reached its maximum, 102°+, on the second and third days. It then gradually but irregularly declined. It was occasionally normal after the first week, but ordinarily 99°+ or 100°, quite up to the time of the patient's discharge from the hospital. The right axillary temperature was the higher twenty-two times, and the left twelve times, and the two were uniform one, in thirty-five observations made during the first nine weeks. The left was afterward usually two tenths to four tenths of a degree higher. The pulse did not exceed 90 after the fourth day, and the respiration was at no time more than 22.

Case XXV.—Male, aged forty years; fell two stories from a fire escape to the pavement below; was conscious and delirious when seen by the ambulance surgeon. There was a small linear wound in the left antero-inferior parietal region, hemorrhage from mouth and nose, and lack of urinary control. Mild delirium and great restlessness continued for twenty-four hours, and the right side and extremities were noted to be warmer and in more active motion than the left. On the second day there was post-cervical rigidity, and the patient became more difficult to rouse. On the third day both pupils were somewhat dilated, the face was flushed, and he lay motionless, with eyes closed, irresponsible to questions or to irritations. On the fourth day post-cervical rigidity disappeared. On the sixth day urinary and fecal control was regained. On the seventh day the patient, fully aroused from his condition of stupor, became restless, and was delirious through the night, but not afterward. From this time he suffered only from mental disorder. He had confusion of ideas and failed to recollect any of the circumstances which preceded his injury, or in fact that he had received a hurt. He had no appreciation of his surroundings, and gave fanciful explanations of his presence in a hospital when interrogated. His mind was alert and his speech coherent. During the second month he suffered an attack of facial crysptalas upon the side opposite the original wound, and was actively delirious. His mental processes were afterward slow, and when questioned he remained long buried in thought before making answer, which when made, though hesitating, was fairly intelligent. He had come to realize that he was in a hospital, but was still ignorant how he happened to be there; "supposed" he had been hurt. The temperature on admission was 97-4°, rose during the day to 102°-, and was afterward usually from 99°+ to 100°+. The right axillary temperature was two tenths of a degree to a degree higher than the left during the first week, and the left the slightly higher of
the two after that time. The pulse and respiration were practically normal at all times.

Case XXVI.—Female, aged twenty-eight years; gunshot wound through right temporal region inflicted during a paroxysm of suicidal mania; ball of thirty-two caliber; primary unconsciousness. On admission three hours later no general symptoms; wound of entrance, half an inch posterior to right external angular process, Y-shaped, three quarters of an inch in length in each of its arms; surface powder-stained, some grains of powder imbedded in the substance of the temporal muscle, but none in the skin; profuse hemorrhage had occurred from the wound and still continued from the mouth and nose; bullet entrance through the bone small and circular and covered by a valve of muscular tissue. On examination the patient was fully conscious, rational, and self-possessed. The right eye was swollen, the lids ecchymotic, and vision on that side entirely lost. The ball had passed from the temporal fossa beneath the lesser wing of the sphenoid and through the floor of the middle fossa at the margin of the sphenoid body. The track was easily followed through the anterior cerebral lobe, and the bony margin of exit could be defined by slightly opening the blades of the short bullet forceps which had been inserted. A small portion of brain matter, not larger than a pea, escaped from the external wound. On the following day she was rather stupid, and another trivial amount of brain matter was extruded. On the third day the left eyelids became moderately ecchymotic and the right side of the face and neck much swollen and painful. There were convulsive movements of the hands and feet, and a loss of smell in the right nostril was confirmed by careful examination. On the fourth day she was quiet and somnolent and had some headache. The left side of the mouth was drawn a little upward and tenderness existed behind the left ear. On the fifth day somnolence and headache ceased, pain and swelling of the right side of the face and neck diminished, and the mental condition became brighter. On the tenth day she was restless and began to suffer pain on the right side of the head, which, on the succeeding day, was intense. The eye became more vascular, swollen, and prominent, and on the fourteenth day was extripated under ether. At the end of a month the bullet wound of entrance had become simply cata-
necous and was in process of cicatrization. The swelling of the right side of the face and neck and the tenderness behind the left ear had ceased to exist. The pain on the right side of the head, which persisted in some degree, was no longer constant or the source of any considerable discomfort. There had been no indication of any form of mental impairment at any time since the slight hebephrenia on the second and third days after the reception of injury, and no loss of facial and urinary control.

The temperature on admission was 100°; rose to 102°4 in twelve hours, and declined to 99°8 on the second day, and then varied from 101°8 to 99°4 till the twelfth day; it did not exceed 100° after the fifteenth day and was subsequently from 99° to 100°. The right axillary temperature was habitually two tenths of a degree higher than the left. The pulse was from 72 to 80 till the third day, from 68 to 52 till the twelfth day, and subsequently from 70 to 78. The respiration was 28 on admission and afterward normal—16 to 22.

In the sixth week the wound had healed and there were no symptoms. At the end of three months her mental and physical condition is normal, in her own opinion better than before the injury was received.

Summary.

The differential diagnosis of the intracranial lesions has been incidentally established in the consideration of their individual symptoms. There are few instances in which the nature of the essential lesion and of its complications can not be determined with substantial certainty, and in a considerable proportion of cases its location even can be fixed with some approach to precision. The fact that an interval of time may be required for the evolution of symptoms is paralleled in the case of idiopathic diseases affecting the great cavities of the body; it can scarcely be considered a special diagnostic difficulty, therefore, in the present class of traumatisms. In lesions of the parenchyma the delay is unimportant; in hemorrhages of the form in which promptitude in diagnosis is demanded by the necessity for promptitude in action, the development of the case is likely to be correspondingly rapid and decisive.

The existence of superficial injuries of the head, the evidences of fracture, and the elevation of temperature, individually or collectively, together with the usual processes of diagnostic exclusion, will be sufficient to determine the fact that some cephalic injury has been suffered. The further determination of the special lesion which dominates the case presents difficulties which, while not insuperable, are often considerable. It is perhaps useless to attempt a more condensed summary of points in differential diagnosis. I have already incidentally stated them as succinctly as seemed compatible with their proper presentation; but it may be of service to recall, or to reiterate, some of the more important diagnostic indications which the study of symptoms has suggested.

Hemorrhages.—The morbid conditions which may directly result from traumatic intracranial hemorrhages are: an abnormal temperature, a complete or partial loss of consciousness, a change in the character or frequency of the pulse or respiration, a disturbance or abrogation of muscular function, and an irregularity of the pupils. These conditions are subject to complication, modification, or super- sedure by the symptoms of coexistent lesions.

A continued subnormal temperature is characteristic of large and comparatively uncomplicated hemorrhages, and as these are more frequently of epidural character, it may be regarded as to a certain extent diagnostic of the variety as well as of the class. The absence of symptoms indicative of parenchymatous injury will be confirmatory of the opinion that an existent hemorrhage is derived from the epidural vessels. Associated symptoms of diffused contusion suggest a pial, and those of laceration a cortical, hemorrhage. In the majority of cases the primary record of temperature is from 99° to 99°+, and in any case in which, then or afterward, it exceeds 101°+, or probably 100°, the elevation is due to an associated lesion. It follows that in pial or cortical hemorrhages the temperature has a higher range than in those of epidural origin, and is proportionate to the extent and importance of the complication. The bilateral variation to which the axillary temperatures are subject is not peculiar to this result of injury.

The primary unconsciousness which is of frequent occurrence in cases of hemorrhage is a symptom of complicating general contusion; the secondary unconsciousness, due to the loss as well as pressure of blood effused, follows with or without an interval of restored consciousness, de-
dependent upon the severity of the diffused injury of the parenchyma and the rapidity of the hemorrhagic effusion, and is partial or complete in proportion to its amount. Consciousness is always lost in fatal cases; it is retained in fifty per cent, and more in recovering cases, even in those demanding operation.

The character and frequency of the pulse have no definite relation to the form, location, or amount of hemorrhage. The pulse may be normal, slow, or frequent in large extravasations wherever situated; but frequency is of so much more usual occurrence in hemorrhage than in other intracranial lesions that when noted it may be considered fairly diagnostic, with the numerical probabilities in favor of its epidural character. The bilateral variation in the force and fullness of the arterial pulsations is common to hemorrhages and to injuries of the brain substance, and of importance, therefore, only in general diagnosis.

An alteration in the character or frequency of respiration is almost invariable in fatal cases in which hemorrhage is an approximately isolated lesion. When the effusion is upon the convex surface of the brain, respiration is usually frequent and often stertorous; when at the base posteriorly, it may be frequent with cyanosis, or, if pressure is made upon the medulla, it becomes progressively slower until it ceases altogether, though cardiac and arterial pulsation may still continue. In recovering cases it is habitually unchanged. In complicated or mixed cases it, like the pulse, perhaps as a result of opposing forces, very generally remains normal; and if abnormal it is more likely to be stertorous than unduly slow or frequent.

General or local paralysis and disordered muscular action may be direct symptoms of hemorrhage compressing or irritating recognized centers of muscular control; tetanic spasm is not infrequent, but clonic contractions are of rare occurrence, except as the result of an associated lesion.

The pupillary condition usually suffers some change, but none which is characteristic. Every possible combination of contraction, dilatation, and normal condition, with the single exception that contraction of one pupil never occurs without some change in its fellow, is associated with every variety and situation of hemorrhage. Dilatation in some combination is more commonly observed than contraction, but not more frequently upon the side of the effusion than upon the opposite; and not more characteristically with one type of hemorrhage than with another. In complicated hemorrhages dilatation of both pupils is more common, and the effusion is more frequently bilateral than in the more nearly simple cases; and in unilateral dilatation is more likely to be on the corresponding side. A normal condition of the pupils is compatible with every variety of hemorrhage wherever situated, whether simple or complicated.

Sensory disturbances, as delirium or irritability, are not symptoms of hemorrhage, and when they occur are to be regarded as indicative of an accompanying lesion of the parenchyma.

Subarachnoid Serous Transudation.—The serous transudation from the pial vessels which occasionally results from meningeval contusion can not be connected with symptoms of other kinds.

Araecephalitis is either acute or subacute in form, and is typically caused by a diffused meningeal contusion, though exceptionally propagated from a point of localized injury. It is sometimes an immediate result of the meningeal lesion, and it may be insidious in its inception and progress, but its beginning is usually late and is sharply defined. Its invasion is likely to be marked by a distinct and rather sudden elevation of temperature and an evident change in the general condition of the patient. The subsequent course of temperature is erratic, and the characteristic symptoms are those of cortical irritation. The pupils are oftener normal than otherwise, and changes in the characters of the pulse and respiration are slight. The form of the effusion is not necessarily reflected in the course and nature of the symptoms. The question of infection is uncertain.

General contusion is a constant complication of all other forms of intracranial injury, but rarely occurs as an isolated lesion of fatal severity. Its symptoms are irregular in their development, course, and termination, and indefinite in their mutual relation. This lack of conformity to any classical rule is due to the comprehensiveness of the lesion, its regional variations, and the fluctuations which occur from time to time in the distribution of the movable fluids upon which its manifestations mainly depend. A loss of consciousness, at some time and in some degree, is more nearly constant than any other individual symptom, and the conditions of temperature are more uniform than any of the other phenomena which it occasions. The temperature is not likely to be subnormal at the time of earliest observation, nor to exceed 99°; its subsequent course in cases of intensity is progressive, with few recessions, and ultimately reaches elevations of high degree.

Primary or early delirium, like primary unconsciousness, in both simple and complicated cases, is to be ascribed solely to the influence of this lesion. The diagnosis must largely depend upon the recognition of the fact of intracranial injury, and upon the further possibility of excluding its other varieties, or, if they exist, of segregating the effects which they produce from a distinct remainder of symptoms.

Limited contusion is comparatively infrequent, and when it occurs in scattered areas through the centrum ovale, is not distinguishable from the general form of the same lesion; when it is cortical, it differs from laceration only in the extent of injury done to tissue; and symptoms, if they result, differ only in degree. It is therefore practically impossible to diagnosticate it from those lesions in their mitigated form.

Laceration is almost, if not quite, invariably complicated by a concomitant general contusion and by a resultant hemorrhage. The primary loss of consciousness, and the delirium of some grade or character which often precedes or follows its restoration, are attributable to the attendant general contusion. In trivial cases there may be no secondary symptoms which indicate the fact of laceration. The primary unconsciousness may be replaced by a condition of
PHELPS: DIFFERENTIAL DIAGNOSIS OF INTRACRANIAL LESIONS.

Jan. 12, 1895.

lethargy or blunted perception, passing through somnolence into coma and death. The primary stage is most frequently succeeded by mental aberration or decadence, which may terminate in recovery, permanent dementia, or death. In exceptional instances consciousness may remain unimpaired, with extensive laceration of even fatal import. There is no necessary relation between the gravity or simplicity of the early psychic symptoms and the outcome of the case.

The temperature is higher than in any other form of intracranial injury, and, in cases destined to an early fatal termination, is characterized by a rapid and progressive increase, which sometimes continues for a certain time after death has occurred.

An irritability or abnormal sensitiveness to external impressions, often noticeable even after the supervision of final unconsciousness, and wanting in cases of hemorrhage or contusion, is of frequent occurrence.

Convulsions, especially in implications of the frontal or temporoparietal lobes, are frequent in fatal cases, and so infrequent in the history of other lesions that they may be regarded as characteristic. The presumption that they are occasioned by laceration rather than by hemorrhage is strengthened by a previous high temperature.

The loss of faecal and urinary control is common to all extensive lacerations without reference to the abrogation of consciousness or of muscular power. It rarely follows other forms of intracranial injury and is very nearly pathognomonic. The urinary and faecal discharges may be either unconscious or involuntary, or they may be the result of the patient’s indifference to his surroundings. There are no demonstrated centers of control.

Paralyses are so much oftener the result of other lesions that they are of service only in determining the location of a laceration the existence of which has been already predicted upon more positive manifestations.

The pupillary changes have no greater diagnostic value than in hemorrhages; the pupils are, in fact, normal in a much larger proportion of cases.

The characters of the pulse and respiration are habitually unchanged unless modified by the existence of complications. The contrast afforded by their substantially normal condition in an environment of pathic phenomena gives them the highest diagnostic value which they possess in this particular relation.

The bilateral variation in axillary temperatures and in the force and fullness of arterial pulsation, already noted as of unknown origin and referred to general diagnosis, is common to all forms of intracranial injury.

The manifestations of psychic disturbance are confined to cases in which the frontal lobes are implicated, but this implication is so constant as to make them practically symptoms of laceration in general. The other special symptoms which localize the seat of laceration have been already summarized.

The phenomena as indicated which directly point to laceration may be enumerated as certain peculiarities of temperature, psychic disturbances, loss of faecal and urinary control, and clonic convulsions.

Pyogenic parenchymatous inflammation is infrequent, and is of limited form, except when caused by the intrusion of a foreign body. Direct laceration and infection through the medium of compound fracture affords no question of diagnosis and is excluded from consideration.

The predisposing cause of traumatic central abscess is limited contusion; the exciting cause is supposed to be the admission of a pyogenic germ from some source external to the body. Though this supposition as to the source of infection may be correct, the further proposition that a route of entrance is always afforded by a superficial wound of the head is erroneous. Cases have occurred and are recorded in which no such wound existed.

The number of instances in which the histories of these limited pyogenic processes have been carefully observed or recorded is insufficient for the formulation of rules for diagnosis. The two cases which I have presented, and a third which I have noted, are in evidence of their uncertain symptomatology.

These conclusions are derived solely from the analysis of the cases which I have detailed, and are stated in as positive terms as the limited number of observations made will warrant. The series of cases presented, if insufficient to afford a basis for statistical inference, is yet so extended that the generalizations which it justifies are entitled to credence until controverted by results obtained from the study of a very much larger number of cases subjected to equally careful examination. It may be questioned whether deductions made, as in this instance, from the comparison of some hundreds of cases are likely to be materially changed by any subsequent multiplication of their number.

Symptoms are so diversified, their combinations so varied, and their continuance is sometimes so brief, that constantly careful observation and equally careful record are essential to thorough comprehension of intracranial injuries. If there are few symptoms which are intrinsically pathognomonic there are many which by mutual relations of time and circumstance assume a pathognomonic character.

The possible multiplicity of lesions must be recognized, the relative as well as the absolute value of symptoms estimated, and if necessary some interval of time afforded for the development of the pathic condition; diagnosis becomes then neither more difficult nor more uncertain than in a majority of grave traumatic or idiopathic lesions.

34 West Thirty-seventh Street.

Changes of Address.—Dr. Albert S. Ashmead, to No. 5 Charlton Street, New York; Dr. Melvin H. Fuller, to No. 117 East Jefferson Street, Syracuse, N. Y.; Dr. R. K. Macalister, to No. 23 West Fifty-third Street, New York.

The Brooklyn Health Department.—Dr. Z. Taylor Emery, health commissioner of Brooklyn, has appointed Mr. William Paul Gerhard, C. E., to the position of honorary consulting sanitary engineer.

A State Examination in Georgia.—We learn that the new law providing for a State board of medical examiners (really, three boards—regular, homoeopathic, and eclectic) went into effect on January 1st.

The Association of Alumni of the New York Hospital will hold its annual meeting at the Hotel Marlborough on Friday evening, the 25th inst., at 8.30 o’clock.
THE USE OF MEDULLARY GLYCERIDE IN CONDITIONS ATTENDED BY PAUCITY OF THE RED CORPUSCLES AND HEMOGLOBIN.

By Allan McLane Hamilton, M.D.

Without making an extended allusion to the organs concerned in the process of corpuscle formation, or repeating what has so often been said before, it may be proper to call attention to the more recent recognition of the importance of the relation of this function to changes in the central contents of the bones. The pathology of the various deprived blood states attended by diminution of red, and commonly increase of white, corpuscles; alteration in form of the former or of the existing proportions of the two kinds of corpuscles; the development of the so-called eosinophile granules; or diminution of cellular contents, has been a matter of some dispute, and clinical states have been ascribed to pathological alterations of the spleen, lymph glands, and medullary contents of bones. Osler's table classifying primary cytogenic anemias has undergone little modification since 1885, when he insisted upon the importance of the medullary changes; in fact, his views have been strengthened by the case reported by Wallace Beatty.

The results of the use of bone marrow by Frazer and others have induced the writer to experiment with this agent during the past few months, and he too has been impressed with its efficacy in certain conditions dependent upon a deprived condition of the blood.

The conclusions reached by the several investigators are not only those which are based upon the general appearance of the patient, but are easily demonstrated by proper and exact tests made with instruments invented by several clinicians and fully described by von Jaksch, so that there can be no doubt of the efficacy of the agent. Extreme care, of course, is necessary in taking the measurements which form the basis of a proper estimate of the extent of cytogenesis which occurs, for all instruments of precision that have so far been devised for measuring the corpuscles and hemoglobin, although approximately correct, very easily exaggerate one way or the other, so that it is necessary to make repeated examinations and take averages, a proceeding at which the patient often rebels, especially if he is nervous.

The cases selected for treatment with bone marrow presented varying forms of red-corpuscle poverty (oligochromia) and diminution of hemoglobin (oligochromienia), most of which were obstinate and had resisted arsenic, iron, manganese, and other hemiants, and in every instance preliminary examinations of a definite kind were made, the red corpuscles being counted by the Thoma-Weiss apparatus, and the hemoglobin estimated by the instruments of Fleischl, Gowers, and Hemoceque. No count was made of the white corpuscles.

The micrometric counts made before, during, and after treatment convinced me that a great proliferation of red corpuscles was possible, the number greatly exceeding the fixed normal standard in some instances, and the daily increase being much more extensive than had been admitted by those observers who have detected a maximum increase of 20,000 or 30,000 per diem after excessive hemorrhage. In two cases the ordinary limit was passed by a million or more, a result which appeared incredible at first, but was proved in a variety of ways, every precaution against error being taken. In this connection Dr. W. Gilman Thompson has recently told me of an experience which has convinced him that both corpuscles and hemoglobin may exist in very much greater quantities than has been supposed to be possible. In two or three cases polkykocytes, or irregularity in the shape of the corpuscles, was present.

It is, I think, reasonable to ascribe this rapid and extraordinary increase to the direct influence of the medullary extract; and the immediate improvement in the state of the blood and subsidence of symptoms, which certainly go together, are no less wonderful than the improvement that follows the use of thyreroidal extract in myxaedema, though the gain is more permanent than in the latter.

Dr. J. S. Billings, Jr., whose conclusions are exceedingly conservative, has employed bone marrow extract in four cases, two of pellagous anemia and two of chlorosis, his reports (unlike those of Frazer) in the former disease being unsatisfactory, while he ascribes the benefits following its use in the other cases to the contained iron—a conclusion which does not seem to be borne out in those cases where red corpuscles are multiplied without any corresponding increase in the hemoglobin.

I made use of two forms of marrow—viz., that obtained from the long bones, which was given raw, as recommended by Bigger; and a glyceride of the short ribs, such as has been advised by Danforth, only the phosphate of sodium and arsenic, which were used by him, and all other substances were omitted.

The writer's preparation, which was made by Frazer & Co., and by Bagoe, of this city, requires that a pound and a half of finely comminuted calves' ribs should be macerated in a quart of pure glycercine, the mass being allowed to stand for several days and frequently stirred. The glycercine is then strained through cheese cloth and given in doses of from one to four teaspoonfuls three times daily, with a few drops of peppermint essence.

I am informed that another preparation has been made

† Vierordt (von Jaksch, p. 7) estimates the average number of red corpuscles in a cubic millimetre at 5,000,000 in health in man and 4,500,000 in woman, with a maximum limit of 350,000 in disease.
‡ A Case of Leucocytamia apparently cured by Bone Marrow, W. G. Bigger, M.D., M. R. C. S. London, September 22, 1894, p. 682.
§ Chicago Clinical Review, vol. iv, 1894.—Editorial in Medical Record, October 27, 1894.
which consists of the emulsification of the marrow by ice-land moss, with a certain amount of boric acid, which is added as a preservative; but the latter is sometimes likely to produce idiosyncratic disorders, so I have confined my patients to the use of the glyceride, which does not undergo any alteration and seems to be as palatable.

Considerable discussion as to the merits of the marrow from the different bones of the animal has arisen. I would say that my best results have been obtained from the red marrow contained in the small bones, notably the ribs of the young animal. The coarse marrow from the long bones contains a great deal of fat, and, while this is, of course, a beneficial nutrient, it would seem that the specific virtues of the agent exist in greater degree in the finer medullary substance.

The glycerides were administered alone and together in cases where no other remedy was given, and the good effects were, as a rule, apparent within a few days, and lasted after the discontinuance of the treatment. In but one case were they not apparent.

**Case I.—Male, aged thirty-six years; ironworker; much debilitated; gradual loss of strength and color for the past six months. The patient has followed his trade in a dimly lighted and badly ventilated cellar; has had malarial fever. Is now, October 18, 1894, very weak; shortness of breath upon least exertion; pulse small and quick; has attacks of tachycardia; no heart murmurs or other evidences of structural cardiac disease; sphygmographic tracing almost without elevations; anxious and melancholic; passes large quantities of clear urine of low specific gravity. His appearance is one of emaciation, and he does not bleed readily. There is a yellowish tinge suggesting icterus, yet no hepatic trouble; spleen somewhat larger than it should be. Haemocytometer gave an average of only 1,000,000 red corpuscles, which were irregular and presented the appearance of poikilocytosis. The white corpuscles seemed to be unusually abundant. Haemoglobin by Henoque's, 87. Iron, arsenic, and cod-liver oil had done little or no good.

On November 1st placed on medullary glyceride.

19th.—Great improvement in strength and appearance; able to work, dyspepsia absent, and walks up stairs without discomfort; pulse greatly increased in volume; in good spirits, and blood-corpuscles average (12 to sq.) 4,800,000; haemoglobin, 10.

25th.—Has gained nine pounds since the first of the month; general improvement in every way, chiefly in appearance; though still pale, "has not felt so well for months." Six countings average (15 to sq.) 6,000,000.

**December 31st.—Has continued to do well.**

This case is probably one of oligochromasia as well as oligocytchymia, for there has not been the corresponding increase in the amount of haemoglobin, von Fleischl's and Henoquete's instruments showing an increase of only 10:50 grams, which is, of course, out of proportion to the exaggerated increase in the number of red corpuscles.

**Case II.—Young woman, aged nineteen years; first seen September 12, 1894; hysterical, anemic; constant besoin de respirer. Very pale, bleeding gums, showness of digestion, and faintness due to atony of stomach and decomposition of food; constipation; small, quick pulse; menstruation has been irregular, and blood thin and of light color and very alkaline. Post-cervical pain, insomnia, and day drowsiness; depressed, and manifest light delusions of a hypochondriacal, erotic, and religious nature; has formed a morbid attachment for a female nurse. Could never take iron. Rest and forced feeding did little or no good.

**October 1st.—Put on medullary glyceride.** Examination showed average of 1,250,000 red corpuscles; blood when drawn had little consistency, flowed too readily, and was of light color. Figures upon Henoque's slide could be read up to nine.

Medullary glyceride given for five weeks gave an increase to over 5,000,000, with thirteen grammes of haemoglobin, and general and steady amelioration of symptoms, which has continued to date (December 11th).

**Case III.—Woman, aged thirty-eight years; exophthalmic goitre; has been under writer's observation for several years, and is a well-marked case. Has at different times suffered from depression, great anemia, tachycardia, loss of hair, bronzing, fur-furcous eruptions, great debility, menorrhagia, respiratory embarrassment, and enlarged thyroid, which latter was somewhat reduced by strophantus, iron, and hydrolic acid; but great exhaustion, anemia, dyspepsia, feeble digestion, and occasional diarrhœa exist.

Medullary glyceride given November 1, 1894; corpuscles average 2,800,000; haemoglobin, nine grammes.

**December 11th.—Material improvement in all symptoms; patient has gained six pounds; pulse, 50; face slightly flushed; can come to office from home, twenty miles in country, and return same day without fatigue and no resulting headache. Increase in corpuscular richness to 5,325,000, and the haemoglobin increasing to 12:20 grammes.

**Case IV.—Woman, aged forty;** for several years has been hysterical, anemic, and incapable of taking exertion without resulting back and headache. A year ago ophorectomy was performed by Dr. Lask, who referred her to me, her nervous state and general malnutrition persisting. A variety of cerebro-spinal neurasthenic disturbances were helped little or not at all by treatment, and it seemed impossible to improve the condition of anemia. Corpuscular poverty well marked, the red corpuscles not exceeding 2,500,000 at any time. November 3d, placed on medullary glyceride with prompt benefit. In doses of two drachms, three daily, she gained over two million corpuscles in six weeks, and her haemoglobin rose to nearly fourteen grammes.

The medullary glyceride was given in fourteen other cases, most of which were without special features, so I will not report them. Suffice it to say that the results were as encouraging as in those reported above.

In cases in which anemic headaches were the prominent feature the effects of the marrow were marked, and many such improved in a few weeks. Two brominized epileptics were decidedly benefited, and this treatment must commended itself when iron in such cases is to produce cerebral congestion and an increase of the fits.

Medullary glyceride was also given to a patient with pulmonary tuberculosis who had been exhausted by severe
hemorrhages, with remarkable resulting benefit, the restoration from prostration being rapid and the ordinary symptoms of the disease improving.

---

SOME OF THE AFTER EFFECTS OF ANTITOXINE.

By J. LINDSAY PORTEOUS, M. D., F. R. C. S. Ed.,
Physician to St. Joseph’s Hospital, Tonkens, N. Y.

At the present time, when not only the medical profession but the general public are deeply interested in the new treatment of diphtheria, it behooves all of us who have had experience in its use to make known to the profession any unusual symptoms which have occurred in our practice after the administration of antitoxine. In looking over some of the reports of observers and experimenters abroad, I notice that urticaria is mentioned as frequently happening during convalescence, a few days after the injection has been made. Sometimes it is ill-defined and sometimes well marked. There is little or no fever accompanying it, although, as is usual in all cases of this nature, there is a slight rise of temperature before the appearance of the eruption. This urticaria is undoubtedly caused by the serum; not necessarily from any poisonous effects of it, but probably, in some cases at least, from an idiosyncrasy on the part of the recipient. It is well known that some people cannot take shellfish without suffering from nettle rash; others cannot take raspberries in any form without the same result. I am given to understand that the serum of certain horses is apt to cause this in certain individuals; therefore makers of the antitoxine are careful to eliminate from their stock any horses whose serum is supposed to have caused an attack of urticaria.

The old saying, "What is one man’s meat is another man’s poison," may be true in regard to serum as well as in regard to food. The amount of injection does not seem to influence those after effects, as I shall be able to show in the cases I am about to mention. The first case I will bring before the readers of the Journal is that of A. B., aged between thirty and forty years.

I was called to see him on the 4th of December. On examination of his throat I found a patch of membrane on each tonsil. A culture was taken from the throat which was found to contain numerous bacilli of diphtheria. For some days previous to the above date he had complained of a sore throat, cough, and feverishness. In the afternoon I injected fifteen cubic centimetres of antitoxine procured from the New York Biological Institute. Sixteen hours after the injection the patches had disappeared, but there was still a deep red, almost purple hue all over the pharynx. A culture was again taken which showed no signs of the bacilli of diphtheria. I injected ten cubic centimetres of the serum. On the following day, the 6th, the throat seemed quite healthy and the patient said he felt quite well. On the 7th his cough was worse and he did not feel so well. On the 8th the condition was much the same. In the afternoon of the 9th he felt decidedly miserable. His temperature was 99.2°. During the early morning of the 10th his whole body was covered with the large, well-known blotches of urticaria, and around the parts where the antitoxine was injected the surface was of a purplish color, to the three inches by an inch and a half. The itching was excessive. During the afternoon the rash suddenly disappeared, but not the redness around punctures. He now became nauseated and had no appetite. I ordered quinine, sulphate of magnesium, and infusion of gentian to be taken every three hours. On the 11th the temperature was 98 4°. The rash had again appeared and the itching was intolerable. This condition continued all day. Toward evening the redness around the puncture began to disappear. To relieve the itching I ordered a lotion containing menthol, alcohol, and water to be applied, also a sixth of a grain of pilocarpine every two hours till free perspiration took place. At 11.30 p.m. the itching was much relieved, but instead of perspiration there was salivation to a great extent; in fact, the quantity of saliva almost choked him. Only one dose of a sixth of a grain of pilocarpine had been given. I stopped this medicine and ordered an alum wash, which arrested the salivation. At 7 a.m. of the 12th, when I saw him, the nausea and itching had entirely left, but he had intense pain in the muscles of his legs, back, and shoulders, with tenderness over left side of abdomen. I ordered five grains of phcenacine to be taken every hour for four hours. In the evening he was to a certain extent relieved, but the pain in the left leg and left shoulder was still very bad.

13th, 9.30 a.m.—He had had very little sleep on account of the pain, which had increased up to 3 a.m. I ordered five grains of salicylate of sodium every two hours as a suborific, as the skin was uncomfortably dry. At 5 p.m. there was still no moisture on the surface of the body and the pain was excruciating, more especially in the left shoulder. I continued the salicylate of sodium and also had turpentine suppos applied to the painful part and gave twenty grains of sulphonal at 10 p.m.

14th, 10 a.m.—The sulphonal procured only an hour’s sleep, but toward morning the pain had much abated and he got more sleep. This, I think, was due to diaphoresis, which had begun at about 5 a.m. In the afternoon he got out of bed, but his limbs would not support him, so he fell on the floor. At 9.30 p.m. was fairly comfortable; gave hypodermic of a fourth of a grain of morphine.

15th, 9 a.m.—Had rested pretty well, but did not sleep. Feels drowsy from morphine. Continued sodium salicylate. At 4 p.m. ordered massage and a draught of bromidia at bedtime, to be repeated in an hour if required.

16th.—Had a better night up to 1.30 a.m. From this time to 3 a.m. pain became much aggravated in legs and arms. The perspiration now being great. I stopped sodium salicylate.

17th, 11 a.m.—Feels much better, but very weak. At 5 p.m. gave a quarter of a grain of morphine hypodermically, as he was anxious to sleep.

18th, Noon.—Pain in shoulder seems bad. Gave a quarter of a grain of morphine. 9.30 p.m., no pain all day after the hypodermic injection. Gave three eighths of a grain of morphine.

19th, 9.30 a.m.—No pain since last night, and no sleep. Gave tonic.

20th.—Shoulder pains a little; otherwise feels well, but weak.

21st.—Very little pain; appetite returned.

22d.—No pain of any account; able to take a drive.

From this time he is convalescent. The urine contained no albumin.

Case II.—Mrs. A. B. On the 14th examined this lady’s throat, and found a patch of membrane on the left tonsil. There was no rise of temperature and no albumin. Gave fifteen cubic centimetres of antitoxine, same as in last case.

15th.—The membrane had partly disappeared. Gave ten cubic centimetres.
SANDBLOM: GYMNASICS AND MASSAGE IN NERVOUS DISEASES.

GYMNASICS AND MASSAGE AS THERAPEUTIC AGENTS IN NERVOUS DISEASES. WITH CASES.

By Gust Sandblom, M. G. (Stockholm).

For many years several nations have endeavored, by the use of different bodily exercises and manipulations, to ascertain the physiological and therapeutic effect of gymnastics and massage. Founded on the experience of different people, there has been arranged a system of gymnastics and massage in which each of the movements and manipulations has a definite end in the treatment of disease.

Gymnastics is divided into four main branches: 1. Medical. 2. Pedagogic. 3. Military. 4. Aesthetic.

Medical gymnastics has a therapeutic purpose—namely, to arrest and combat diseased conditions—while, on the contrary, the purpose of pedagogic gymnastics is to develop healthy people.

According to types of the antique, medical gymnastics is divided into active and passive movements: active (free or made under resistance), when the patient himself takes a working part in the movement; passive, when the patient does nothing, and the movement is executed on him or with a part of him. Massage manipulations belong to the latter class.

We see the strengthening and animating effects of exercise on the nervous system daily. Compare the laborer, whose work requires hard bodily exercise, with the class of society whose vocations require little or no bodily exercise. How often do we hear the latter complain of symptoms which are the commonest companions of nervous debility, while the laborer rarely presents any symptoms of nervous debility in its true sense!

In order to explain the physiological action of the active movements upon the nervous system we must remember the intimate relation in which the muscles stand to the nerves. When an active movement is to be executed, the will impulse is carried through the motor nerves from the brain-cells to the muscles. Through the co-operation of the peripheral nerves the movement is perceived by the brain. By this muscle contraction nerve centers and peripheral nerves have sprung into activity. The contraction has produced a muscle pressure on the blood and lymphatic vessels. The elastic walls of the arteries are able to resist this pressure; the strength of the blood-pressure in them and the semilunar valves at the opening of the aorta prevent regurgitation of the arterial current. The soft and flexible walls of the veins yield, their valves pointing toward the heart, and the slight blood-pressure in them assists the muscular pressure in accelerating the venous current. By means of this is produced a pressure of the venous blood toward the heart, a suction of the lymph toward the veins into which it is emptied, and thus an acceleration of the arterial circulation. Therefore a richer material has been carried to the active muscles as well as to the nerves.

According to the science of physiology, by inactivity a nerve becomes debilitated, passes through a process of degeneration, and at last loses all irritability; but by activity a nerve becomes strengthened and hardened. Therefore the efficacy of active movements in debilitated conditions of the nervous system can readily be seen.

The physiological effects of the passive movements upon the nerves, especially those of direct mechanical irritation, have in recent years received the attention of prominent men of science, among whom are Zabljadowsky, Tiggerstedt, Mosengeil, Zederbaum, and Wide. Physiological facts show that the effect of a mechanical irritation of a nerve not only acts during its application, but also continues after it has been withdrawn. The irritability of a nerve increases in proportion to the amount of pressure applied up to a certain point. After this point has been reached the irritability of the nerve diminishes and at last ceases. This is demonstrated by pressure on the neck, between the internal jugular vein and the carotid artery, on the vagus, where a strong pressure causes an inhibition and even stagnation of the beat of the heart. By pressure on the neck over the phrenic nerve cramp of the diaphragm is suppressed, and by static pressure on the other motor nerves cramp and tremor in the respective muscles disappear. Extension of a nerve causes contraction of the neurilemma and thus propagates a pressure on the axis cylinder through the
SANDBLOM: GYMNASTICS AND MASSAGE IN NERVOUS DISEASES

The movements must be adapted thereto. As an example of the technique, I will describe a nerve vibration. After the operator has, by palpation, found the nerve, ganglion, or plexus which is to be vibrated, he puts the muscles of his fingers, arm, and shoulder into a state of tension, and produces in this condition, in the long direction of the arm, vibrations of the nerve, raising the rate to three hundred a minute, and even more. These vibrations are so extremely fine that a spectator who places his hand on the muscles of the operator’s arm scarcely perceives any motion of them. During these vibrations the operator lets the tips of his fingers slide along a nerve or be fixed on a ganglion or plexus, determining for each case the amount of pressure necessary.

The great difference between real medical gymnastics and pedagogic exercises and between medical gymnastics and common massage treatment can be shown best by the following cases, in which the patients had been treated, not only with pedagogic exercises, but also with common massage, without the slightest success:

December 20, 1893, I was sent by a physician to treat a case of neurasthenia caused by overwork. The patient, a lawyer, forty-nine years of age, was then, on account of increased weakness and pains, obliged to take to his bed. He suffered from slight dyspeptic symptoms; complained of constant fatigue, incapacity to work, sleeplessness, headache, failing appetite, and intensely painful gastric conditions. Palpation showed nothing abnormal save a trigeminal neurailgia, the supraorbital nerves swollen and painful, especially on the right side. (Neuralgia in the right arm, caused by rheumatic myosis, disappeared after the removal of the myositis.) The treatment was begun on December 21, 1893, and nerve vibration was first given over the supraorbital and dorsal sensory nerves, nerve vibrations over the solar plexus, respiration movements, together with other suitable passive movements. Gradually day by day more vigorous treatment was given, and the patient began by degrees to take stronger active movements.

The above-mentioned painful gastric conditions disappeared after the first treatment and have not since returned. The patient was improving rapidly, and continued during the treatment his usual professional activity. The treatment, which was interrupted twice by the patient taking business journeys, was ended on May 15, 1894, when all symptoms of diseased conditions had disappeared, and the patient declared himself to be perfectly recovered.

Before I took charge of this case the patient had, among other remedies, tried pedagogic exercise at a gymnastic institute, and in the course of it had grown worse.

On January 2, 1894, I was sent by another physician to treat a case of hypochondriasis. The patient, a college professor, seventy-eight years old, had suffered from his complaint for thirty years, and was very feeble. The sleep was extremely poor, and had for a long time been obtained by means of narcotics, which were used two or three times during the night. The appetite was good. The patient’s mind was very much depressed; he was hypochondriacal and uneasy, and dwelt continuously on the condition of his health. He had during a long time not had any spontaneous evacuation of the bowels; this had been obtained exclusively by means of laxatives used daily. The patient complained of heaviness in the head, pressure and pain in the epigastrum. By palpation there was noticed dilatation of the stomach, with soreness on pressure in the epigastrum and over the sigmoid flexure, the colon being abnormal, dis-
tended, and filled with excrement, and there was prolapsus ani. The treatment was started at once, and he was first given nerve vibrations over the occipitalis major, shaking of the stomach, friction over the colon, and vibrations after effleurage around the protruding anus, in connection with other suitable passive movements. Day by day as the patient improved the treatment was altered, and he gradually diminished during this time the narcotics and laxatives until they were unnecessary, and he had daily spontaneous evacuations of the bowels and enjoyed natural sleep. The treatment was continued until April 28th. The patient had then completely recovered, the bowels moved regularly, the stomach was in a normal condition, the pain had passed away, the prolapsus had gone back, and the hypochondriacal symptoms had totally disappeared. The patient felt completely well.

As in the preceding case, before I assumed the care of the patient, he had tried the common massage treatment by two skillful masseurs, but without effect.

Several similar cases could be cited here if the space allowed, but those mentioned show us clearly that by the manual treatment of nervous diseases the patient is not cured by means of irregular mass exercises, or by a thorough kneading of his whole body; but there is required a systematic course of treatment based on physiological phenomena.

Every movement, every manipulation, demands the whole ability and care of the instructed operator.

What medical gymnastics signifies I have briefly explained, and will now refer to its method and therapeutic effect on some of the most common peripheral and central nervous disorders.

Against neuralgia and neuritis experience shows that the manual method is a powerful weapon, and this is most clearly illustrated through the following statements:

In the treatment of supraorbital neuralgia and migraine, not only the supraorbital nerve, but also the supra trochlear, nasal, superior maxillary, mental, auriculo-temporal, and occipital should be examined by palpation. By palpation are observed painful and swollen parts of different nerves, especially of the supraorbital near the supraorbital foramen and of the auriculo-temporal and occipital, and usually marked soreness on pressure over the first cervical sympathetic ganglion. The treatment consists of vibrations over the painful and swollen parts of the different nerves, nerve friction over the first sympathetic ganglion, and other passive and active movements, which are determined by the circumstances of the case, and at last effleurage should be given in the direction of the venous current.

In this case, as in neuritis of the facial, congestion of the brain, and similar disorders, I have often found the pain diminished and a general recovery follow the first treatment and become complete after a few applications. The harder cases require, on the contrary, more work, and sometimes the treatment must be continued for weeks before good results can be obtained.

At this point I will say that for ordinary headache I never need to apply more than a few minutes' nerve vibration to have the headache disappear.

In a great number of cases of peripheral nervous disorders found, by means of palpation, to be caused by myositis (rheumatic, etc.), the inflammatory processes or pressure of the swollen muscles cause alteration in the action of the nerves. It is often observed that a nerve resumes its normal activity after the myositis has been worked away by means of the manual method. An illustration of this fact is seen in sciatica when caused by myositis. In this neuralgia the patient is placed during examination in such a posture that the muscles are relaxed, thus facilitating palpation of the muscles as well as of the nerves. The palpation is executed with the greatest care on all the muscles along the nerve, and in the course of it there may be noticed, where the acute myositis is found, a soft swelling, diminished elasticity, doughy consistence, and pain on pressure. Where the chronic myositis is found, there are observed larger or smaller indurations in the otherwise perfectly normal muscle substance. By means of friction and effleurage the myositis is removed, nerve frictions are applied along the nerve, the patient is given proper active movements, and the treatment is ended with a nerve extension.

By applying this manual method in cases of sciatica, when the patients, in consequence of pain day and night, can get neither sleep nor rest, I have many times after the first treatment heard them declare that the pain had nearly disappeared and they have enjoyed good sleep. It is, however, not sufficient that the pain should give way temporarily, the myositis must be entirely removed, and the treatment must not stop until all palpable alterations have disappeared. Acute myositis requires only a few applications of the treatment, but chronic myositis requires of the operator hard and energetic work, sometimes continuing through several weeks.

Medical gymnastics can, in disorders of the central nervous system, raise the condition of the nutrition and give back ability of function to muscles which, by central nervous alterations, are so enervated that they have even ceased to react to electric irritation. Therefore it may readily be understood why the active and passive movements should be used in treating this class of disorders. Experience teaches us, too, that by means of the manual treatment the diseases accompanying sensory disorders, such as anæsthesia, hyperæsthesia, paresthesia, etc., disappear, that spasm gives way, that ataxy in the movements in high degree is acted upon, that the sleep, the appetite, and the whole general condition are improved. The therapeutic effect of medical gymnastics on the central nervous diseases is most clearly shown in tabes dorsalis. In its treatment nerve pressure is first given over the different nerves where the pain has appeared, the abdomen is treated with pêtrissage and effleurage, the bladder with vibrations, the dorsal sensory nerves with nerve frictions, and moderately active movements are given; all the muscles receive pêtrissage and tapotement, and the treatment is ended with general effleurage. Although this treatment requires hard and careful work, and must be given to the patient every day, sometimes lasting for several months, often such good results are gained that they inspire confidence in those who before had little faith as to the value of this method, especially in the more advanced cases of these diseases.
Among others, the following central nervous diseases have been treated with success by medical gymnastics: Chronic myelitis, hereditary ataxy, sclerosis cerebro-spinalis multiplex, spastic spinal paralysis, progressive muscular atrophy, chorea, graphospasm, etc.

By the above-mentioned facts I may have attained my purpose—namely, that of giving the reader an idea of the technique and the therapeutic effect of medical gymnastics in the treatment of different nervous disorders.

14 West Thirty-third Street.

SOME CASES OF
INFLAMMATION OF THE FRONTAL SINUS,*

BY F. N. G. STARR, M. B. (TOR.),
SENIOR ASSISTANT DEMONSTRATOR OF ANATOMY, TORONTO UNIVERSITY.

It is said that in all cases of coryza a congestion of the lining membrane of the frontal sinus occurs. The cases I am about to relate are not those of simple congestion, but are some that presented well-marked signs of inflammation. The ages of the patients varied from twenty-three to thirty-one years. In the first case the patient had contracted a cold, and nine days afterward, when almost well, he commenced to suffer from headache, which became rapidly worse. In the second case there was a history of cold seven days previously, the headache recurring and becoming worse; and in the two other cases the patients had a mild attack of influenza ten days previously, the headache, one of the earliest symptoms, persisting from the first and continuing. The condition began with a sensation of soreness, which the patient referred to either the right or the left eyebrow, according to the side affected. Subsequently the pain was described as gnawing in character and gradually increasing in severity, with exacerbations upon stooping, coughing, sneezing, etc. There was a constant desire to clear the nose, though usually there was no discharge. At intervals, however, a large quantity of material would be evacuated, after which there was considerable relief for a time. If the patient slept, he would be awakened in an hour or two by a recurrence of the pain, but, upon rising and evacuating the contents of the sinus, he would again be fairly comfortable. In passing I may say that, if the infundibulum is patent, bending the head forward and slightly to one side materially assists in emptying the sinus. The accumulation in the sinus was discharged through one nostril only; it consisted of a thick, yellowish, muco-purulent material, and was blown from the nose in large quantities, but, as I have said, only at intervals. Tenderness on pressure over the affected sinus was marked; there was a peculiar sign, and one that I am unable to explain satisfactorily—namely, extreme tenderness on pressure over the tubercle for the pulley of the superior oblique muscle of the eyeball. Edema of the skin over the affected side occurred in two of the cases, and in one there was some drooping of the eyelid. The temperature was elevated from half a degree to a degree and a half Fahrenheit above the normal; the pulse but little accelerated.

As the attack subsided the discharge gradually became less purulent and more mucous-like in character. The pain disappeared, but there persisted for some days a sense of fullness upon stooping, sneezing, etc.

Internally, in all the cases a brisk cathartic was administered; externally, in three of the cases "mustard leaf," cut into one-inch squares, was applied over the affected side, with directions to reapply at the end of ten minutes, and so on. Relief came within an hour, and a reapplication on that or any subsequent day was unnecessary. The other patient, a woman, not liking the idea of some temporary disfigurement, preferred to use turpentine as a local application; but, though it did relieve the condition, the effect was by no means so speedy. Complete recovery took place in five, three, seven, and eight days, respectively.

These cases I have seen during the course of the past three winters. It is said that "it never rains but it pours," and it would seem that the proverb had again scored a victory, for last spring I saw no fewer than three undoubted cases in one day. Each patient gave a history of cold some weeks before, and added that when he was recovering from it a headache had developed which had gradually become worse and persisted. There was increased pain on stooping, etc., with an intermittent discharge from the nose. The patients were disabled from work.

One of these, a woman, was afraid of the disfigurement that would result from the use of mustard, and used instead hot fomentations and a nasal douche with very happy results. The others used the mustard as before described, and were promptly relieved. When I heard from them a few days later they were still free from the headache, etc., and were able to resume their various occupations. The discharge from the nose, however, continued for some days, though in diminished amount. This was to be expected, for the cases did not come under observation until some time after the onset of the trouble.

The ages in this last series ranged from thirty-five to forty years. This is an interesting feature, and I am inclined to think that the disease occurs only in adult life. As a matter of fact, it can not occur in very young children, for there is no sinus in which to develop until near puberty.

You will remember that I drew attention to the marked tenderness on pressure over the pulley of the superior oblique muscle. It is said that "supraorbital neuralgia is hardly ever absent in inflammation of the sinus"—whatever the term neuralgia may mean. Perhaps in this case it means an inflammation of the sheath of the supraorbital nerve. If this is the case, surely it is possible for the trouble to extend to another branch coming from the same trunk—namely, the supratrochlear—which, as you know, escapes from the orbit between the pulley of the superior oblique and the supraorbital notch.

I think I was fortunate in having to deal with cases in which the infundibulum remained patent, for when stenosis occurs one never knows just how long his treatment may be required, and he does not know of the complications and sequelae against which he may have to contend.

* Read before the Simcoe County Medical Association.
REMOVAL OF A
LEAD PENCIL IMPACTED IN THE AXILLA.
IN A CASE PREVIOUSLY MISTAKEN
FOR ONE OF FRACTURE OF THE CLAVICLE.

By SINCLAIR TOUSEY, A.M., M.D.,
SURGEON IN CHIEF, ST. BARTHOLOMEW’S CLINIC:
INSTRUCTOR IN CLINICAL SURGERY,
POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL:
ASSISTANT SURGEON, ROOSEVELT HOSPITAL, OUT-PATIENT DEPARTMENT.

This patient is a colored boy about sixteen years old, from whom I removed a lead pencil four inches long, which had been mistaken for six weeks for a necrotic fragment of the clavicle.

The patient came to the Out-patient Department of the Roosevelt Hospital on the last day of February, 1894, presenting a sinus in the axilla and one below the middle of the clavicle, and a probe introduced into either sinus encountered a hard, rough surface suggestive of necrotic bone. He said that six weeks previously he had fallen and hurt his shoulder very badly; that he had been attended immediately by two physicians, who said that his collar bone was broken; and that they had applied suitable bandages. In the course of the next four weeks a very large swelling formed below the clavicle and another in the axilla. After examination at a number of hospitals he was admitted, as a ward-patient, in one of the largest hospitals in the city. This was about ten days before I saw him. There the two large abscesses were incised, but it was decided not to attempt to remove the necrotic fragment until a later date. The boy’s mother then removed him from the hospital and brought him to Roosevelt Hospital for treatment.

I found that the hard fragment was freely movable when pushed upon by the probe, and also that pressure in the axilla was transmitted to the hard fragment below the clavicle. It was then perfectly clear that some kind of a spike had been driven into the axilla and broken off after penetrating so far that its point could be felt below the middle of the clavicle.

The sinus below the clavicle was enlarged and the lead pencil withdrawn, to the very great astonishment of the patient and his friends. The sinus passing from the clavicle to the axilla healed promptly under the use of permanganate-of-potassium irrigation, and no impairment of function has resulted.

The entrance of the lead pencil is very easily explained; the boy had climbed a lamp-post to light his bicycle lamp, and his feet slipped off the ornamental ledge which passes horizontally around the post about four feet from the ground. As he fell a lead pencil in his waistcoat pocket caught on this ledge and was driven into the axilla and broken off out of sight.

29 West Thirty-Eighth Street.

The Jefferson Medical College of Philadelphia.—Many members of the class of 1879 are desirous of having a class reunion on the occasion of the fifteenth anniversary of their graduation. Owing to changes, comparatively few addresses are known, and therefore this means is resorted to with the hope that every member of the class of 1879 who reads this notice will communicate at once with the class president, Dr. Philip R. Koons, Mechanicsburg, Cumberland County, Pennsylvania.

The New York Academy of Medicine.—Executive officers have been elected as follows: President, Dr. Joseph D. Bryant; vice-president, Dr. William M. Polk; recording secretary, Dr. Reginald H. Sayre; corresponding secretary, Dr. M. Allen Starr; treasurer, Dr. O. B. Douglass (re-elected).

* Patient shown at a meeting of the Surgical Section of the New York Academy of Medicine, November 12, 1894.

NEW YORK, SATURDAY, JANUARY 12, 1895.

THE FOURTEENTH ANNUAL REPORT OF THE NEW YORK STATE BOARD OF HEALTH.

Two large volumes and a third volume of maps comprise the report for the year 1893. It was transmitted to the Legislature last February, and has just been issued from the press. It begins with a résumé of the work that was done to prevent the spread of cholera, should it enter the country, and due credit is given to the active and efficient co-operation by the government inspectors abroad at ports of embarkation. The board properly considers that this work resulted in other good than merely preparing for an epidemic, because it stimulated interest in preventive medicine.

The death-rate for 1893 was 19.50; in 1892 it was 20.78; in 1891, 21.43; and in the two preceding years, 19.65. The months of March and July had the highest death-rates, while June and November had the lowest. The mortality among children under five years old was 33.6 per cent. of the deaths at all ages; those of the preceding years were respectively 33.5, 34.5, 36.6, and 38.6. Zymotic diseases caused 180 deaths in each 1,000 deaths from all causes, the ratio for preceding years being 182-87, 178-0, 169-0, and 206. The mortality from typhoid fever, scarlatina, measles, malarial diseases, and tuberculosis was less than in former years, while that from diphtheria, whooping-cough, cerebro-spinal fever, and acute lung diseases was greater.

During the year 20,310 cattle were inspected for tuberculosis, at an average cost of forty-seven cents for each animal, and 687 were killed because they were tuberculous. In this work the hypodermic administration of tuberculin is employed, and it has been proved that a rise of two degrees Fahrenheit above normal temperature is suspicious, and that a greater rise almost invariably indicates tuberculosis. One fourth of a cubic centimetre of lymph is injected, and for eighteen hours thereafter the animal is not fed or watered. Eight samples of butter were examined bacteriologically, some of which was made from milk obtained from cows known to be tuberculous, but no bacilli were found. This evidence is unreliable as an indication that tubercle bacilli do not occur in butter, for bacteriological examinations of butter purchased at random have shown that ten per cent. of the samples contain tubercle bacilli.

Some two hundred pages in the first volume are devoted to plans for systems of sewerage and sewer disposal in towns and villages and investigations of sewerage nuisances. The five hundred and ten pages of the second volume are devoted to a detailed report of the inspection of herds, including the data relating to each cow injected with tuberculin.
MINOR PARAGRAPHS.

THE TEMPERATURE DURING OTHER ANÆSTHESIA.

The Medical Week for December 14th publishes the following conclusions of Dr. Angelesco: 1. During the whole time anaesthesia lasts, the temperature falls, so that the hypothermia is proportional to the duration of the anaesthesia. 2. The variation in the temperature is much more marked at the beginning of anaesthesia than subsequently; the difference is found to be most marked during the first and second fifteen minutes. 3. The fall in temperature continues, though in a slight degree, during the deep sleep following the anaesthesia. 4. The temperature begins to rise at the moment of waking, and proceeds in a ratio inverse to the fall, so that the rise becomes more and more marked as the patient becomes more completely awake. The fall in the temperature under the influence of ether has been attributed to increased radiation of the uncovered parts, to the immobility, and to slower oxidation and lessened absorption of oxygen. While Simonin and Kappeler found that the temperature might fall decidedly during chloroform anaesthesia, Dastre considered that etherization lowered it still more, and Angelesco's studies seem to confirm this idea. The latter thinks that the temperature difference following the administration of these anaesthetics is due to the fact that ether causes vaso-dilatation, while chloroform produces vaso-constriction.

THE MEDICAL SCHOOL OF COLUMBIA COLLEGE.

It is announced that the Medical School of Columbia College, commonly known as the College of Physicians and Surgeons, is to profit by further benefactions at the hands of the Vanderbilt family, amounting to more than half a million dollars, to be used in enlarging the anatomical rooms, the Vanderbilt Clinic, and the Sloane Maternity Hospital, besides additional sums to equip the new portions of those departments. In some of its features, we have reason to think, the anatomical department is already quite equal to any in the world, and, with the fresh resources now to be placed at its command, we see no reason why it should not soon be unsurpassed in every respect. The school as a whole is admirable and steadily progressive. As we have often said, it is not the school alone or even the medical profession that profits by such munificent gifts, but the whole community as well.

URANALYSIS VERSUS "Urinalysis."

The Medical News, of Philadelphia, closes a review of Dr. Charles W. Purdy's excellent work on Practical Uranalysis with this remarkable sentence: "By a strange perversion, the compositor has insisted upon spelling urinalysis 'uranalysis.'" We fancy the compositor is not to be credited with the appearance of the word in its correct form, but rather Dr. Purdy himself. At all events, there is properly no such word as urinalysis.

McGILL UNIVERSITY, MONTREAL.

It is announced that Dr. William Osler, of the Johns Hopkins University, Baltimore, has been called to the presidency of McGill University. Dr. Osler is a Canadian by birth and early training, and it will be but a rendering back of her own to Canada if he accepts this new appointment. While we recognize this, we shall none the less regret the loss to the profession in the United States.

AN INVESTIGATION OF THE DIPHTHERIA ANTITOXINE TREATMENT.

The announcement that the Bureau of Medicine and Surgery of the Navy Department has ordered Passed Assistant Surgeon Cordeiro to study the subject of the therapeutic value of the antitoxine treatment of diphtheria, and to report to the department, is of good augury. The matter is one that should be studied with the guidance of official responsibility.

ITEMS, ETC.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending January 8, 1895:

The Late Dr. John W. Pinkham.—At a meeting of the Orange Mountain Medical Society of New Jersey, the subjoined resolution was passed, a copy of which was ordered to be sent to Dr. Pinkham's family and to each of the following journals: The Medical Record, the New York Medical Journal, the Montclair Herald, and the Montclair Times:

The Orange Mountain Medical Society of New Jersey learns with deep regret of the death of Dr. John W. Pinkham. Dr. Pinkham was born in Gardiner, Maine, was a graduate of Haverford College, Pa., and of Bellevue Hospital Medical College, New York. He began the practice of medicine in Montclair in 1867, and was so engaged until 1890, when, by reason of ill health, he was compelled to give up active work. He died on December 7, 1894, of apoplexy. He was the author of numerous articles on hygiene and preventive medicine.

Dr. Pinkham was a charter member of the Orange Mountain Medical Society, and continued an active and earnest member until his resignation, on account of ill-health, in 1892. The society greatly regretted his loss and elected him an honorary member. His work on Intubation of the Larynx will long be remembered by his associates. It is the wish of this society to express its deep sorrow for his death and to show its earnest sympathy for the bereavement which has befallen his family.

[Signature]

Jeffords Hunt, 
John J. J. Love, 
William H. White, 
Committee.

The Medical Society of the County of Dutchess, N. Y., held its annual meeting in Poughkeepsie on Wednesday, the 9th inst., under the presidency of Dr. J. H. Doughty. The programme included a paper on The Diagnosis, Complications, and Treatment of Hypertrophic Rhinitis, by Dr. Edward J. Berningham, of New York; and a demonstration of Bassini's
operation for the radical cure of hernia, by Dr. Samuel E. Miliken, of New York.

The Diagnosis of Diphtheria.—The following special announcement has been issued from the Laboratory of Bacteriology of the Philadelphia Polyclinic: "As the early diagnosis of diphtheria from other pseudo-membranous affections of the throat has always been a matter of difficulty, and in some cases of absolute impossibility, the consensus of opinion is that it can be made with certainty only by a bacteriological demonstration of the presence or absence of the Klebs-Loeffler bacilli. Furthermore, the question of the association of other pathogenic and of pyogenic microbes with the Klebs-Loeffler bacillus is of importance in prognosis. In view also of the introduction of the blood-serum therapy, an early and absolute diagnosis is imperative in testing the efficacy of such treatment. The Laboratory of Bacteriology of the Philadelphia Polyclinic is ready to undertake this examination and to report to physicians the bacteriological diagnosis of suspected cases. Sterilized swabs and blood-serum tubes, together with instructions for the method of procedure, can be obtained at the laboratory or from Mr. W. S. Leffman, in the faculty's office. The results of the examination will be reported within twenty-four hours from the time of the return of the tubes. This service is gratuitous."

The Third International Dermatological Congress will not be held this year, as proposed. The time of meeting has been postponed because the British Medical Association meets in London this summer, and it was feared by the executive council of the congress that the autonomy and international character of the congress would be imperiled by holding its meeting at the same time and place, also that the necessarily divided interests of the British dermatologists would prevent that full exercise of hospitality to their foreign visitors that they so much desire to extend.

As the next meeting of the International Medical Congress will be held in Moscow in 1896, it is possible that the Dermatological Congress may not be held until 1897. The foreign secretary for the United States, Dr. George Thomas Jackson, of New York, who has kindly furnished us with the foregoing information, adds that as soon as he hears definitely from England as to this point he will write us again.

The New York Orthopedic Dispensary and Hospital.—The eighteenth annual course of clinical lectures by Dr. Newton M. Shaffer began on the 7th inst., and will be continued on Monday and Thursday afternoons, at five o'clock, until February 21st. The course is free to the medical profession and students.

The City Board of Health.—It is announced that Dr. Charles S. Benediet has been appointed to succeed Dr. Doty as chief of the Bureau of Contagious Diseases.

Army Intelligence.—Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from December 30, 1893, to January 5, 1895:

Matthews, Washington, Major and Surgeon. The leave of absence granted on surgeon's certificate of disability is extended four months on surgeon's certificate of disability.

Naval Intelligence.—Official List of Changes in the Medical Corps of the United States Navy for the week ending January 5, 1895:

Bradley, Michael, Medical Director. Detached from duty as a member of the Naval Examining and Medical Boards.

Kinder, B. H., Medical Director. Ordered as a member of the Naval Examining and Medical Boards.

Parker, J. B., Surgeon. Ordered to special duty in connection with the investigation of the Ford Theatre disaster.

Stone, Lewis H., Passed Assistant Surgeon. Promoted from Assistant Surgeon.

Cordeiro, F. J. B., Passed Assistant Surgeon. Ordered to study the subject and make a report to the department of the therapeutic value of antitoxine in the treatment of diphtheria and croup.

Marine-Hospital Service.—Official List of the Changes of Stations and Duties of Medical Officers of the United States Marine-Hospital Service for the Sixteen Days ending December 31, 1894:

Prentice, George, Surgeon. Relieved from command of the service at Philadelphia, Pa., and detailed as Medical Inspector of Immigrants at that port. December 18, 1894.

Peckham, C. T., Passed Assistant Surgeon. To inspect unserviceable property at San Francisco Marine Hospital. December 26, 1894.

Kalloch, P. C., Passed Assistant Surgeon. To proceed to Bureau for special temporary duty. December 29, 1894.

Bratton, W. D., Passed Assistant Surgeon. Placed on "waiting orders," to date from January 1, 1895. December 26, 1894.

Perry, T. B., Passed Assistant Surgeon. To proceed to New York, N. Y., for temporary duty. December 28, 1894.

Perry, J. C., Passed Assistant Surgeon. To proceed to Philadelphia, Pa., and assume temporary command of service. December 18, 1894.

Procaccia, Emil, Assistant Surgeon. Granted leave of absence for twenty-five days. December 17, 1894.

Society Meetings for the Coming Week:

Monday, January 14th: New York Academy of Medicine (Section in General Surgery); New York Academy of Science (Section in Chemistry and Technology); New York Medico-Historical Society (private); New York Ophthalmological Society (private); Lenox Medical and Surgical Society, New York (private); Boston Society for Medical Improvement (annual); Gyneacological Society of Boston; Maine Academy of Medicine (Portland); Burlington, Vt., Medical and Surgical Club; Norwalk, Conn., Medical Society (private).

Tuesday, January 15th: New York Academy of Medicine (Section in General Medicine); New York Obstetrical So-
MARRIAGES AND DEATHS.—LETTERS.—PROCEEDINGS OF SOCIETIES. [N. Y. MED. JOUR.]

Societies (private); Ogdenburgh, N. Y., Medical Association; Syracuse, N. Y., Academy of Medicine; Medical Societies of the Counties of Kings (annual) and Otsego (semi-annual—Cooperstown), N. Y.; Connecticu River Valley Medical Association (Bells Falls, Vt.; Baltimore Academy of Medicine.

Wednesday, January 16th: Medico-legal Society; Northwestern Medical and Surgical Society of New York (private); New Jersey Academy of Medicine (Newark); Philadelphia County Medical Society.

Friday, January 18th: New York Academy of Medicine (Section in Orthopaedic Surgery); Baltimore Clinical Society; Chicago Gynaeological Society.

Saturday, January 19th: Clinical Society of the New York Post-graduate Medical School and Hospital.

Births, Marriages, and Deaths.

Married.

Wannamaker—Bamberg. In Bamberg, S. C., on Sunday, December 30th, Dr. Edward J. Wannamaker and Miss E11ie Bamberg.

Died.

Attinelli. In Vineland, N. J., on Tuesday, January 1st, Dr. E. J. Attinelli, in his sixty-third year.

Goldthwaite. In New York, on Thursday, January 3d, Dr. Henry Goldthwaite, aged fifty-two years.

Hall. In Robinson Springs, Ala., on Thursday, December 27th, Dr. Thomas D. Hall, aged sixty-five years.

Kurtzman. In New York, on Monday, December 31st, Dr. Edward J. Kurtzman, aged twenty-four years.

Marx. In Washington, D. C., on Thursday, January 3d, Dr. George Marx, in his fifty-fifth year.

Puel. In Houston, Tex., on Wednesday, January 2d, Dr. M. Perl.

Roof. In New York, on Wednesday, January 9th, Dr. Stephen W. Roof, aged fifty-one years.

Letters to the Editor.

ANIMAL EXTRACTS.

Washington, D. C., January 8, 1895.

To the Editor of the New York Medical Journal:

Sir: Will you kindly allow me to state in the New York Medical Journal that I have no connection whatever with the so-called "Institute for the Administration of the Animal Extracts" advertised in the New York Tribune of Sunday last, that it was established without my knowledge or consent, and that I did not even know of its existence till I saw the advertisement referred to. Whether or not the layman who advertises that he gives consultations and administers the extracts violates the law is a question for the consideration and action of the County Medical Society.

William A. Hammond, M. D.

THE LOCAL EMPLOYMENT OF COPPER ARSENITE.

Middletown State Hospital, January 5, 1895.

To the Editor of the New York Medical Journal:

Sir: I beg you to let me say a few words in reply to Dr. John Allde's letter in the last number of your esteemed Journal. Dr. Allde claims priority in the local use of the drug. I would not deny it. Estimating from his records, he was the first to use it locally; but does that interfere with the individuality of my researches in this respect and experience? I have not been acquainted with The Pocket Pharmacy; it is impossible for a man in general practice to keep acquainted continually with all the medical literature of our State even; and consequently there can not be a single idea entertained as to the injustice of my article.

It is quite natural that several minds should be led at the same time to the same or very similar conclusions regarding one and the same object, and we see instances of it continually here as well as abroad. Let us give to a few scholars the same problem, and if they are able to follow the normal ways, even if these differ, they all will reach the same result, for this, being the only true one, is the only one possible. Hence, Dr. Allde, let us have no controversy about priority in our work or articles. The aim of both, I am sure, has been the same and impartial, and I do not esteem your work any less for my little intervention. What I found and wrote was honest and independent of you or others. I have carried the application of the remedy somewhat further still, applying it to the different forms of aphthulosis, which will prove, I hope, with others and you, as it did and still does with me, one of its most important fields of action; and I have ventured a theory as to the explanation of its action, which, too, you will admit, I could not have received from others. Let us, therefore, give up all trouble as to who was the second and who first, and, instead of on that, spend our time in further investigation and trials of the remedy as to whose value we both agree so perfectly.

A. H. H. HEDLICKA, M. D.

THE CONJOINT USE OF KUMYSS AND MATZOOX.

31 West Thirty-Eighth Street, January 8, 1895.

To the Editor of the New York Medical Journal:

Sir: I not infrequently find patients who dislike kumyss on account of its acid taste, and who object to matzoon because it lies heavy on the stomach. This has led me to try a mixture of the two, and for some time I have used a mixture of equal parts of these two articles of diet, and with such satisfaction to myself and patients that I venture to call attention to it. I believe such a mixture is not only more palatable but more nutritious than either preparation when taken by itself.

John H. Girdner, M. D.

Proceedings of Societies.

SOCIETY OF ALUMNI OF BELLEVUE HOSPITAL.

Meeting of November 7, 1894.

The President, Dr. C. C. Barrows, in the Chair.

Sarcoma of the Superior Maxilla.—Dr. Parker Syms presented a patient with this condition. Mary O'11—, seventeen years of age, had come to him on account of a tumor of her upper jaw. The family history and her own previously had been good, and there had been no evidence of syphilis or of tuberculosis. The mother had stated that the first set of teeth
had developed properly and had been complete, but that the left eye tooth of the second set had never developed. Three years ago there had appeared a small swelling on the gum, which had steadily grown ever since. It had caused little or no pain. Examination had shown an absence of the upper canine and two bicuspid teeth on the left side and the presence of a well-marked tumor of the superior maxilla. The latter had diluted the bone so as to deform the cheek. The alveolar surface had been thinned, and the mucous membrane separated on each side by a fungous mass which occupied the position of the missing teeth. This tumor had had all the appearances of a new growth, and had probably been a sarcoma; however, it might have been due to a retained tooth. A piece had been removed from the fungous mass and submitted to microscopic examination. Nothing but granulation tissue had been found. A further examination would be made, and then the proper operative treatment would be decided upon. If it proved to be a sarcoma, the entire maxilla would be removed; otherwise more conservative means would suffice.

Dueshrsen's Method of Deep Cervical Incision for Rapid Delivery.—Dr. J. Clifton Edgar presented a specimen and photographs and read the following notes of a case in which this method had been practised:

A. B., aged twenty years, primipara, unmarried, was admitted into the Emergency Hospital, June 11, 1894. According to the statement of her friends, for two weeks prior to her admission to the hospital she had been rapidly failing, suffering from headache, nausea, and vomiting, and quickly grew so weak that she was unable to do her household work. Upon the morning of June 11th the patient was taken with severe headache, nausea, and vomiting; later she was seized with convulsions, and during the day she had three convulsive attacks. During this time she was seen at her home by a physician, who is said to have administered morphia.

At 9.40 on the evening of June 11th, the patient was brought to the hospital by ambulance, being at this time in coma, she having just passed through a convolution. She was assigned to a ward, and a vaginal examination was followed by another convolution. The os uteri was found to just admit the tip of the index finger; the supravaginal portion of the cervix had almost disappeared, and, as far as could be determined, the woman was not in labor, being in the middle of the ninth month of gestation. The head presented in the lower part of the uterus. The pupils were symmetrically contracted; legs oedematous to a point above the knees; pulse full and hard, a hundred and forty to the minute; temperature, 105°; fetal heart sounds were distinctly heard an inch and a half below and to the left of the umbilicus; the catheter failed to obtain any urine from the bladder and a simple enema was followed by good results. Chloroform was at once administered to control the seizures, but in spite of its use the patient passed through five distinct convulsions in the fifty-five minutes following her admission to the hospital.

At 11.43 p. m., after thorough antiseptic preparation of the vagina and external genitals, and the woman being now under the influence of chloroform to the surgical degree, four deep cervical incisions were made after the method recommended by Dührsen, anteriorly, posteriorly, and laterally, from the free border of the external os to the utero-vaginal junction. Blunt angular scissors were used for the operation, the scissors being grasped in the right hand, and the first and second fingers of the left hand were used as guides, the second within and the first without the lower uterine segment. By means of these four incisions full dilatation was immediately secured, the vaginal walls being now continuous with those of the lower uterine segment, four loose, nearly triangular flaps only intervening.

The left hand, as the vertex had been made out to the left, was now readily passed into the uterus, the membranes were ruptured opposite the feet, the anterior leg was seized and brought down into the vagina, and the child was extracted. Both arms unfortunately went above the head, and some difficulty was experienced in the delivery of the after-coming head, which was finally accomplished by suprapubic pressure and jaw-traction. The difficulty with the after-coming head was partly due to a slightly flattened pelvis, as the true conjugate measured at the autopsy was a scant four inches. The child was extracted and the cord clamped at 11.52 p. m., just nine minutes from the time the first incision was made.

The child, a male, weighed seven pounds and a quarter, was rather deeply asphyxiated, and was finally resuscitated after a quantity of what appeared to be liquor amnii had been aspirated from its larynx and trachea by means of a small English catheter, an attempt at respiration on the part of the fetus having evidently been established prior to or during the operation. The child, as far as known, is alive to-day. The placenta was expressed and the uterus and vagina were irrigated. Sharp haemorrhage followed the incisions until the hand and forearm were introduced for version, but no post-partum bleeding of consequence took place.

The after-treatment consisted of high enemata of castor oil, glycerin, and sulphate of magnesia; of nitroglycerin and stimulants by the mouth and needle and the hot-air bath. During the hour between 3 and 4 A. M. of June 12th, the bowels moved freely twice as the result of the high enemata. At this time it was reported by the nurse that the patient passed a small quantity of urine, but none could be obtained by catheter before or after the operation. Small quantities of hot water were administered every few minutes, and in this way several pints were given. In addition, a pint and a half of hot normal saline solution was injected into the back and thighs. Two marked convulsions occurred after the emptying of the uterus, the first two hours and the second three hours after. To control these, chloroform was used. Oxygen was administered at short intervals, and, after swallowing became impossible, stimulants in hot water were given per rectum.

The lowest temperature recorded was 102° F., and this was at 9 A. M. of June 12th. Afterward the temperature rose again, and at 3 p. m. death occurred, fifteen hours after delivery, the patient never having regained consciousness after her admission to the hospital.

Autopsy.—June 13, 1894, twenty-three hours after death. Body well nourished; edema of lower extremities extending above the knees; a small quantity of serum in the peritoneal cavity; the fundus of the uterus was found on a level with the umbilicus, the right horn being nearest the anterior abdominal wall. The lungs were congested and oedematous, otherwise nothing abnormal was found in the lungs or heart. The brain was not examined. In the left broad ligament, beginning at its base and extending up for two inches between the folds, is readily made out a fresh extravasation of blood, moderate in quantity, rather causing a staining of the tissue than an actual clot. Without opening the uterus the whole genital tract from fundus to perineum was removed. The exact length of the true conjugate was then found to be slightly under four inches. The parts being laid upon the table, with a pair of blunt scissors an incision was made from the anterior commissure of the ostium vaginae, along the anterior vaginal and uterine wall nearly to the fundus uteri. The isthmo-rectal portion of the fundus uteri was then removed. The implantation area was then removed. The implantation area was then removed. The implantation area was then removed. The implantation area was then removed.
and the other of that of an almond. The gauze being removed, the cervix uteri and the four incisions, clearly defined, were brought into view, and the whole genital tract was then photographed after being submerged in water. [The photographs and specimens were then presented to the meeting.] A few drachms of urine or serum were found in the bladder, but, unfortunately, the liquid was lost before being examined. The kidneys were large, soft, mottled, with smooth surface, non-adherent capsules, and blood flowed freely from the cut surfaces. They were sent to the laboratory for microscopic examination, and Dr. H. S. Stearns has most kindly photographed one of the sections, which shows the condition of acute parenchymatous nephritis.

Dr. S. Marx said that this was the first post-mortem specimen from such a case that he had seen. It only served to prove the feasibility of the operation. Where incisions were made sufficiently deep, tearing of the cervix was out of the question. It had never occurred to Dührssen or to any one else who had made these incisions sufficiently deep. In his original paper Dührssen had stated that incisions should be made up to the utero-vaginal junction. The indications for this operation were very numerous according to his original paper, but in a more recent contribution the field of the operation had been greatly restricted by its originator. It should never be done except in cases presenting extreme emergency as regarded the child or the mother. Certain well-known obstetricians in New York had stated that they had never seen a case in which the operation had seemed to be indicated; but it seemed to him that in cases such as acute eclampsia with threatens fatal results it was certainly indicated. He had had six cases where the operation had only been done under the strictest indications; in all but one he had saved both mother and child. The first case had been that of a young woman pregnant with her fifth child. The cervix had been rigid from cicatrical tissue. He had tried ineffectually with his fingers, with powerful seel dilators, and with Barnes’s bags to dilate the cervix, but failed; and, as the coma had been rapidly deepening, he had incised the cervix, and had quickly extracted the child by pedicle version. There had been a frightful hemorrhage immediately after making the incisions, but this bleeding had come from the uterus and not from the cervix. The uterus had been tamponed and the hemorrhage completely controlled.

If the incisions were not made fully up to the utero-vaginal junction there was sure to be a tear extending up so far as possibly to involve the circular artery, and perhaps even the uterine artery. The so-called Skutsch’s operation was irrational and dangerous. He had been surprised to read in a recent book on obstetrics by Dr. Grandin that the author recommended this operation, but said nothing about Dührssen’s incisions. A number of superficial incisions were made in Skutsch’s operation, radiating outward, and if further operative measures were instituted there were likely to be several deep tears, not only of the cervix, but extending into the broad ligament, associated, perhaps, with severe hemorrhage. In the Dührssen incisions suturing was a very simple matter if it was indicated for hemorrhage, which, however, was seldom if ever the case. The point of greatest resistance was at the internal os—namely, above the cervico-vaginal junction; hence, if the incisions were made before the supravaginal portion had dilated, merged into the lower uterine segment, they would extend into the broad ligament, causing serious bleeding. Manual dilatation should be resorted to until this stage had been reached. The so-called elective accouchement would give excellent results in suitable cases, but in cases of grave emergency he knew of no operation which would accomplish so much as Dührssen’s.

Dr. Egbert H. Grandin said that he would premise his remarks by saying that, as this practice was only as yet on trial, he might be obliged later to retract what he was about to say. At present he had found no field for this operation of Dührssen’s, notwithstanding the brilliant results which had come to us from Germany, as well as from this country. He was afraid of the operation. It was certainly one that he would not choose, and which he would hesitate to do so long as there were other methods which were safer for the mother and just as safe for the child. He was never willing to accept statistics from foreign sources; he was awaiting home results, and so far these had not been sufficiently numerous to lead him to adopt this procedure in his practice. He had met with almost every complication in obstetrics, and he had yet to see a case in which it had seemed to him that these incisions were called for, or in which he had not had sufficient time to dilate the cervix manually under deep, surgical chloroform anesthesia, which also controlled the eclampsia. Under these circumstances he had usually been able to deliver the woman of a living child. If he should see a case where the emergency was so great that he could not wait for manual dilatation, which had hitherto accomplished everything for him, he would be disposed to perform Caesarean section, as being preferable to these deep incisions. The Caesarean section, when done aseptically, carried with it absolutely no more risk to the woman. It could be done by the non-expert, and within the nine minutes which Dührssen’s incisions, followed by version, had occupied in the case just reported. Notwithstanding the thirty-six cases reported by Dührssen, the four by Marx, and the one by Edgar, he felt that these incisions were very apt to extend farther than was desired. Where manual dilatation had not allowed him to get access to the uterus quickly, the difficulty had always been in the supravaginal portion; hence the Dührssen incisions would not be applicable. For these reasons he had not made reference to Dührssen’s operation in the new book on obstetrics which he had written for teaching purposes, and to which allusion had been made by Dr. Marx. He had had good results from the superficial incisions, and hence he would continue to teach this method. He had not seen these superficial incisions followed by tearing or extension of the incisions, while they had proved valuable in his individual experience. The tribunal of last resort was, of course, our individual experience; and hence this was his reason for not adopting Dührssen’s incisions, and his reason for adhering to the superficial incisions in his teaching and practice.

Dr. W. R. Pryor said he had done the operation only once. The patient had been a primipara, and his object in doing it had been similar to that in Dr. Edg’s case. The operation had been rapidly performed, the hemorrhage had not been of importance, and the cervix had not been sutured afterward. He considered Dührssen’s incisions of the greatest value, and would prefer them to accouchement forcé. As for Caesarean section in these cases, he would not for a moment consider it.

Dr. Marx asked Dr. Grandin what he would do if called upon to attend a multiparous woman with a cicatrical os, on whom all the usual methods of dilatation had been faithfully tried without avail. He felt sure he would have hastened the end by subjecting his patient to a Caesarean section. His patient had been seen in private practice, and had belonged to the middle class of people.

Dr. Grandin replied that what he would have done would have depended largely, of course, upon his assistant, but in all probability he would have thought only of Caesarean section to fulfill the indications in eclampsic coma—viz., to empty the uterus. It did this much more quickly than any other method; it also enabled us to bleed the woman, and much more freely than by incision into the uterine. He certainly would do Caesarean
section in hospital practice—if necessary, with a pocket knife. Moreover, he thought he would have saved at least the child, whereas Dr. Marx had lost both woman and child.

Dr. Edgar said that he had not the slightest desire to make light of the operation; he felt sure it was only applicable to such desperate cases as the one in which he had just performed it. It was well known that in about ninety per cent. of cases of eclampsia the convulsions ceased on emptying the uterus, and he knew of no quicker way of emptying the uterus than by Dührssen's incisions followed by version. He was positive that in this particular instance he had assisted to laparotomy he would have lost the child. The time necessary for preparing for the operative procedures that had been undertaken in the case cited had only been a few minutes. He had done the operation three times; two of the women had been in coma, and in one there had been repeated convulsions.

(To be concluded.)

COLLEGE OF PHYSICIANS OF PHILADELPHIA.

SECTION IN GENERAL SURGERY.

Meeting of November 9, 1894.

Dr. John B. Roberts in the Chair.

Wood-pulp Splints and Splint-making Material.—Dr. William J. Taylor read a paper with this title, and presented a number of splints made from a new material, the invention of Dr. Edward A. Tracy, of Boston. All of these splints had been made by Dr. Tracy, and had been in actual use at the Boston City Hospital. Dr. Tracy had written to the author that the results to be obtained would repay the trouble of acquiring the proper technique, and this trouble was but slight.

The material had been best described, said the speaker, in Dr. Tracy's article, entitled A Brief Splint-technology for Surgeons, which appeared in the Medical News for March 17, 1894, and of which the following was a abstract: The basis of the material was wood-pulp, made preferably from the crushed fiber of the poplar tree, and rolled in such fashion that the broken fibers intertwined in every direction and loosely, so that an increase of plasticity was thus given the product. These sheets were further strengthened by having a fabric introduced between the layers of the pulp, or by interleaving with the short, crushed wood-fiber a long jute or other tough fiber. The sheets were rolled of different thicknesses, and were numbered one, two, and three, according to their thickness in millimetres. The chief characteristics of this material were stiffness or rigidity when dry, and plasticity when moist. Its rigidity could be increased ad libitum by the use of a silicate solution as a moistener. Its plasticity had a limit, but this was rarely reached except when molding the material over certain complex curved surfaces. Besides the foregoing characteristics, the material possessed that desideratum of a splint-material—extreme lightness. Its cheapness also deserved a passing mention.

Water or a stiffening solution could be used to moisten the material. If water was used the splint must be protected from the perspiration, lest it should soften, by a covering of oiled silk or paper, or best by shellac. A stiffening solution with several qualities to recommend it was that of silicate of potassium; silicate of sodium was almost as serviceable. Any desired degree of rigidity could be imparted to a splint by using this solution, the amount of rigidity depending upon the strength of the solution. Dextrin in the proportion of eight ounces to a pint of water added some tenacity besides stiffness. A splint made with its aid could be moistened with water and remolded—quite an advantage in many cases.

In using this material the aim should be to get barely sufficient moisture to render the material semi-plastic. If more moisture was absorbed it became difficult to maintain the molded splint in the desired shape while drying, and it also unnecessarily lengthened the time required to dry it. The best manner of moistening the splint-blank was to apply the fluid well on each side of it alternately by means of a flat paste brush. A little practice would enable one to judge of the precise amount of moistening best suited to the purpose. The time required for drying the molded splints varied from ten to forty minutes, according to the thickness of the material used; any source of heat could be employed; a kitchen fire was serviceable and nearly always at hand.

While drying the splint after it was molded to fit the part, it was well to wind a bit of yarn or string around it to aid in retaining its shape until it was sufficiently hard to keep its form.

Dr. Tracy had also described in detail the application of splints made from this material to different portions of the body, including the head, the trunk, and the upper and lower limbs.

As the speaker had only recently received the material his personal knowledge of the technique was limited, but he said he could readily see the ease with which the sheets could be molded to fit inequalities in the limbs. The extreme lightness of the splint would be of the greatest service in many cases, and it would be much more comfortable to the patient than the heavier and more cumbersome splints in common use. Then, too, by coating the splint with a silicate solution, it became impervious to moisture and could be washed daily with an antiseptic solution.

Thyroidectomy in the Treatment of Goitre.—The Chairman read a paper on this subject in which he said that his object in bringing this topic before us was to call attention to the ease with which the enlarged thyroid gland could be enucleated, and the mechanical symptoms caused by its pressure removed. After medical treatment had been employed sufficiently long to make it evident that no important change in size was to be expected, it seemed to him that thyroidectomy need not be delayed.

Perhaps two months was as long as one need wait, if during that time the approved remedies had been employed in full doses. It must be remembered, he said, that goitres not infrequently varied in bulk without relation to medicinal treatment; hence a diminution was not necessarily the result of the local or internal medication. If dyspnoea, due to pressure on the trachea, was marked, or if hoarseness from compression of the recurrent laryngeal nerves was present, one month's unsuccessful treatment by medicines would probably induce him to operate.

Parenchymatous injections of alcohol, tincture of iodine, or other irritants did not seem sufficiently successful or free from danger to be adopted as a routine, though cases might still come under his care in which he should be willing to try them. Tapping or incision and packing of cystic goitre were available; but, after the former, the cyst was apt to refill, and the latter operation made almost as much scar as thyroidectomy, and was not much less serious. Electrolysis did not seem to have given sufficiently certain results to make it attractive. Tracheotomy might be demanded when tracheal compression was marked, though in some cases subcutaneous or open division of the deep cervical fascia, to allow the bronchocoele to bulge forward, would avert the threatened suffocation.

Division of the thyroid isthmus to lessen pressure, and ligation of the thyroid arteries to cause atrophy or prevent increased growth, were operations almost, if not quite, as serious as removal of a portion of the diseased gland.

The speaker referred only to thyroidectomy, or removal of a portion of the thyroid glands; total extirpation was unwar-
ranted, because the occurrence of myxedema as a result of the entire loss of the thyroid gland was pretty well established, experimentally and clinically. The most disfiguring and most compressing part of the goitre might be removed, and a portion of one lobe left to carry on the function of the gland. He would do this even if the part left was apparently not healthy to the naked eye. It seemed pretty well established that a small portion of the gland, or a small accessory gland, if such was present, was sufficient to avert the occurrence of myxedema in patients subjected to removal of goitrous masses.

Thyroid feeding, the administration of thyroid extract, or the implantation of the thyroid gland of one of the lower animals in the connective tissue or the peritoneal cavity of patients previously subjected to extirpation of the gland, might overcome the tendency to myxedema, but until this was really proved the surgeon should do only a thyroideectomy, and leave a portion of the gland in position.

He did not go over the steps of the operation in detail, as they were sufficiently clear to any operator, he said, who was prepared to deal with sharp hemorrhage, and who was careful enough to avoid injuring the recurrent laryngeal nerves. A vertical incision was made in the median line of the neck or above the most prominent part of the tumor, and the necessary portion of the fibroid, cystic, or hypertrophic gland enucleated. Perfect asepsis or antisepsis was essential.

The enlarged thyroid in exophthalmic goitre had been subjected to operation, but the general character of this affection would deter him from operating upon the bronchocele, which was only one symptom of the disease, unless further statistics showed its value in an unmistakable manner.

The speaker reported two cases to illustrate the subject. Neither goitre had been of great size, but both had been annoying to the patients. They had been radically cured by operation. The enormous fibroid goitres seen especially in Europe would, of course, be more difficult to deal with, especially in regard to the control of bleeding.

Dr. G. A. Mühlecek said he had a case under observation at present with a well-marked hypertrophic goitre which he was treating after Garé's method, which was practiced at Professor Brun's clinic at Tübingen. It was the parenchymatous injection of iodiform in a solution of ether and olive oil, the proportions being seven parts each of olive oil and ether and one part of iodiform. Under this treatment the measurements of the enlarged gland were diminishing rapidly. Garé had published the clinical records of from twenty-five to thirty cases in which this method had been carried out with exceedingly gratifying results. The author was speaking, however, only of the hypertrophic form.

Dr. W. J. Taylor asked if Dr. Roberts had noticed any special respiratory difficulty or nervous shock in his operations when working near the sheath of the vessels of the neck or in deep dissection. In two cases which had come under his observation the patients had been operated upon for goitre; everything had seemed to be going on well, when suddenly, during the dissection, in which there had been no hemorrhage of any account, one of the patients had had some respiratory difficulty and rapidly sunk, dying in a few hours without any obvious reason.

Dr. G. G. Davis said there were cases of goitre in which the tumor was not very deeply seated and did not go below the sternum and the great vessels, so that it could be easily shelled out, and the hemorrhage was almost nil. In other cases the hemorrhage was very marked. He had seen one case where the patient had died upon the table from it. This had happened in the hands of a surgeon of the highest skill. Therefore, he thought that the seriousness of an operation depended upon the kind of case it was rather than upon the operation or the surgeon, and accidents might happen in the hands of any one.

Dr. Shoemaker had been present at one of the operations reported, and had been very much pleased with the skill shown by Dr. Roberts in managing the hemorrhage by carefully securing the bleeding vessels. It had been one of those thyroids which were not very adherent, and did not descend much below the border of the sternum. The special point of interest to him had been in seeing how easily such growths came out when skilfully attacked.

Dr. Davis said that if these had been cases of intraocular enucleation he would be much interested in hearing about the bleeding and how it had been controlled. The substance of the thyroid gland and veins in these cases was so extremely friable that it was almost impossible to control the bleeding by the application of hemostats. They simply tore out; they would not hold at all. Dr. Wolff, of Germany, had advocated the intraocular enucleation of the enlarged thyroid gland, and the method he had recommended had been practically to bite away the growth piecemeal, controlling the hemorrhage by means of pressure. It took exceedingly skilful manipulation to perform a thyroideectomy without hemorrhage by such a method, and most of the other surgeons who had discussed his paper preferred Kocher's method.

The Chairman said he did not work inside the capsule, but principally outside. He cut down outside of the capsule and shelled out the tumor. The operation was extracapsular, except where the capsule was accidentally cut through during the operation. Of course, the goitres were much smaller here than the goitres seen in Europe. In the greatly enlarged glands the vessels were increased in number and size, as well as the tissue elements. He had seen a comparatively large number of goitres at the Woman's Hospital, and he had refused to operate upon a good many of them. It seemed to him, however, that where there was dyspnea or pain from pressure upon the vessels of the nerves by the growth it was proper to operate. In many cases relief could be obtained by medicine, and if we could succeed in taking the patient's mind off from the goitre, the enlarged gland would give less trouble. The cases reported, it seemed to him, had been proper ones for operation. With regard to Dr. Taylor's question, the speaker had seen profound collapse during an operation upon the neck, although not in a case of goitre. There had been sudden stoppage of breathing and serious circulatory disturbance. He found that he had been making pressure upon the pneumogastric nerve, and as soon it had been relaxed the breathing had become normal.

(Book Notices

How fully the editor's intention, to present a complete review of the subject up to date, has been accomplished will easily be seen by a comparison of the indices of this with those of works upon this subject published several years previously. For
example, a work published in 1882, and at that time the most complete upon this subject in the English language, mentions sixteen varieties of erythema, twenty of eczema, and eight of alopecia, while in the present work we find thirty-six, twenty-six, and fifteen varieties of these diseases respectively.

These minute divisions of the subject and refined distinctions between similar though not identical affections show how careful and extensive has been the study of dermatology in the past few years. They are useful, no doubt, from a scientific point of view to the specialist, but to the general practitioner they may tend rather to confuse than to assist. In the coining of names dermatology has been the most active of all the specialties. Admitting that the advancing knowledge of the pathology and etiology of diseases justifies the giving of names indicative of their nature, we still think that the nomenclature in this branch of medicine could be much simplified and shortened.

The present work, however, has not undertaken to reconstruct the subject. The editor has taken it as it came from those best qualified to speak upon its different branches, and arranged the various contributions into a symmetrical whole with rare ability. The contributors are all American practitioners, and in the list may be found the names of most of the prominent dermatologists of this country. Of those portions of the work contributed by such prominent writers as Fox, Robinson, Hardaway, Bronson, Van Harlingen, and Morrow, there is nothing but praise to be written. Their names guarantee a thorough consideration of all that is known upon the subject and trustworthy advice to follow in the management of those diseases of which they treat. Among the more recent authors who have contributed to this volume the work of some deserves special mention. The anatomy and physiology of the skin have been handled by Dr. Louis Heitman in a manner unequalled in any other work of this character. The text and illustrations of this section are as near perfect as it seems possible to make them, and the editor is to be congratulated upon his fortunate selection of an author for this section of the book.

The article upon lymphangitis, including lymphangiec- tasis, has been contributed by Dr. C. F. Hersman. His descriptions are concise, lucid, and to the point.

The articles by Dr. Fordyce, Dr. Elliot, Dr. Allen, and Dr. Hartzell all deserve special mention. That by Dr. Fordyce, on leucokeratosis buccalis, should be read by every practitioner, as the disease is not commonly understood and often erroneously treated.

The relations of the Bacillus tuberculosis, the psorosperm, and other bacilli to skin diseases having been established, a readjustment of old classifications has been rendered necessary; this has been done throughout the work, and any one reading it may be assured that he is getting the latest pathological and therapeutical knowledge upon the subject.

The mechanical construction of the work is worthy of the highest commendation. The woodcuts and the colorotype and half-tone plates are of the most artistic character, and make almost an atlas of skin diseases in themselves.

We have thoroughly enjoyed the reading of the second edition of Dr. Abbott's book, for it possesses that quality so rare in medical literature (and in fact in technical writings generally) of being interesting and readable. Its clearness, too, is delightful, and, though for the bacteriologist it would be elementary, for the student and the practitioner, for whom it is intended, it may well be doubted if the work could have been more admirably done.

To this opinion, which applies largely to the first edition as well as to the second, must be added a commendation of the additions to the work which appear in this last edition. The chapter on infection and immunity is wisely introduced and the story of our knowledge of these important subjects is concisely and excellently presented. The introduction of colored cuts, too, is a valuable addition, and the cuts are so colored as to convey their information forcibly and well, and are not, as is too often the case, gaudily overdone.

The author states that he has taken advantage of the publication of a fifth edition of his work to add a section on mental diseases so as to increase the usefulness of the volume.

It is one of the most practical works of this character that have been published, and it is surprising how much information is contained within its pages. Necessarily the treatment of any topic is concise rather than comprehensive, but the definitions are good, the symptoms are sufficiently detailed, and the treatment recommended is judicious.

The present edition is likely to continue the popularity that the work has evidently enjoyed.

A work which aims at conciseness should not be condensed at the expense of completeness where detail is necessary. This is intended to be used as a text-book, yet whole pages are taken up with irrelevant information, while vague and indefinite statements are constantly made regarding important matters.

There are other and better American books, and such English works as those of Parkes and Wilson, which are concise and yet complete.

In the chapter on air two pages are given to an inferior method of bacteriological examination, and the best process is not mentioned.

Food is much better explained in the text-books on physiology.

"Normally, saprophytic bacteria are present in milk in considerable numbers," says the author, citing Flügge, but not his latest results.

"A temperature of 212° F. maintained for thirty minutes will kill all bacteria as well as their spores," she says. This is not true. These are fair examples of loose statements constantly made in this work.

The chapter on the causes and prevention of infectious diseases should be the most important part in a book on hygiene, yet in this instance a rare disease such as anthrax is given a page, while neither measles nor erysipelas receives more than six lines.
In conclusion, typographical errors and errors of expression abound, such as "some nutrient media is," "diffusible," "Petrie's" for Petri's, and "excretas was."

A more thoroughly practical and valuable handling of the subject than is done in this edition of Dr. Mosckett's book would be indeed a difficult task. Both in the part of the work dealing with drugs and in that on applied therapeutics the matter is concise, well arranged, and useful in the highest degree. For the general practitioner, as well as for the specialist, the book will be of great value.

While fully appreciating the spirit in which this little book is written (for it is a kindly consideration of educational institutions in America, and especially of medical schools and hospitals), we are somewhat amused "to see ourselves as others see us."

The information imparted is in the main correct, though often so brief and condensed as scarcely to do justice to the subject: but some things are rather startling, as witness the French rendering of the name of one of our prominent surgeons, "M. M. C. Burnet."

By New York practitioners the space accorded the Sym's Operating Theater will perhaps be appreciated, and certainly the author's frank admiration of that building (he says it "is truly a surgical palace") will be gratifying.

The book is rather more interesting than the impressions of us held by foreigners usually are.

The report for 1892 is full of interest, and, indeed, so valuable is the matter contained in it that it must arouse regret that, with all the material at the disposal of American hospitals, so few of them make that material of service to the profession by the publication of similar reports.

Abstracts of exceptional cases are an interesting feature of these reports, and in the present volume cases of beri-beri, infective endocarditis, myxodema, and primary carcinoma of the liver may be mentioned as of special interest. In the chapter on pneumonia our attention is called to the supposed favorable import of herpes facialis in that disease by the statement that in the nine cases in which it was noted there were no deaths.

This little volume is the result of the collaboration of twenty-four Paris physicians who are connected with the hospitals of that city, and it contains more than four hundred opinions on divers and sundry measures for treating various diseases. It is intended to permit the educated physician to recall the methods he saw practiced when he was a student and during his hospital service, as well as to give those who have long been away from their alma mater a resume of recent therapeutic measures.

The reader may find the more recent methods of treating anthrax, cholera, diabetes, diphtheria, erysipelas, eruptive intermittent and typhoid fevers, gangrene, gon, malarial disease, morphinism, obesity, rhachitis, rashes, scarring, serofulosis, tuberculosis, and many other diseases.

Those who consult the book are likely to find advice from one whose name is in itself sufficient authority for the therapeutic measure recommended.

Sodium Salicylate in the Treatment of Acute Articular Rheumatism.—In the Journal des praticiens for December 22d there is an article on this subject by M. Henri Huchard in which he says that there are three things to be strictly observed in the administration of this remedy: 1. It should be prescribed in large quantities from the beginning of multarticul ar rheumatism. 2. These quantities should be divided into small doses. 3. Its administration should be continued after the pains have ceased.

Some physicians, says the author, prescribe progressively increasing doses, but to do this is to lose time, and it is an error in medical tactics which may be prejudicial to the patient. From the beginning, at least ninety grains of the salicylate must be given daily, and this amount should be continued for about two days, when it may be decreased every two or three days until sixty grains have been reached, thus insuring success, for in an adult thirty or forty-five grains are not sufficient. If there is high fever, a hundred and twenty grains may be prescribed, but it is useless and even harmful to exceed this dose.

With regard to the early administration in large quantities, M. Huchard says that experience has shown that its action is all the better the when rheumatism is acute and recent, also that early treatment prevents cardiac complications, which are often manifested on the fourth or fifth day, and not always after the eighth or tenth day, as was formerly believed. The administration of this remedy should be urged all the more since, although it may prevent endocarditis and pericarditis, it has no action on these complications once they have been established. Certain physicians, Bondet, for example, say that sodium salicylate is capable of producing a certain cardiac erosion which is not without influence in the production of endocarditis. This is an error, says M. Huchard. The remedy has no action on the heart except when given in a toxic dose. The same thing may be said in regard to cerebral rheumatism, which has become very rare since the employment of sodium salicylate, which prevents its occurrence as it may prevent endocarditis, pericarditis, and even rheumatic pleurisy.

For children this remedy has a still greater importance than for adults, says the author. In the latter, the articular manifestations must be many; there must be a great deal of rheumatism in order to produce, ordinarily, cardiac complications. In the child the heart acts as an articlenion, according to Bouinlou; slight rheumatism with scarcely any fever, or a simple torticolis, is sufficient to cause rather rapid endocardial complications. The pains are sometimes so vague that, at a certain age, they are called growing pains. From the time that rheumatism manifests itself, even in its most attenuated form, the salicylate should be prescribed and aspiration of the child's heart frequently practiced.

M. Huchard prescribes the following doses: For children under a year old, from eight to fifteen grains; for those between two and five years, thirty grains; for those of six years, forty-five grains; for those between six and ten years old, from forty-five to sixty grains; for those over ten years, from sixty to seventy-five grains.

With regard to the administration of the remedy in small doses, M. Huchard says: 1. Medicines that are eliminated slowly, such as digitalis and morphine, for example, should be given in a single large dose, because the organism charges itself with the division into small doses. 2. Medicines that are quickly eliminated should be given in small and repeated doses, if its desired to make a longer and more complete impression on the organism. Now, sodium salicylate is a medicine that is eliminated almost as rapidly as the iodides. It manifests itself in the urine in from five to six minutes after its administration, and it takes, in ordinary cases, from twenty-four to forty-eight hours to become eliminated, that is, when the kidneys are not affected with organic or functional insufficiency.

It is not alone the nature of the medicine, says M. Huchard, or its facility of elimination which should indicate its adminis-
MISCELLANY.

The administration of this remedy, says M. Huchard, should be continued in smaller doses for at least twelve days after the pains have stopped; sixty grains, then forty-five, being given, in order to avoid a relapse. For the rest, the rule is the same as that followed in the employment of quinine sulphate after intermittent fever.

In a serious and infectious form of articular rheumatism, it may be observed occasionally that the pains disappear almost completely, but the fever persists; from this it may be seen, says the author, that the sodium salicylate produces its anesthetic effect, but that it is not capable of producing its antirheumatic action. In this case auscultation must be practiced often, and the employment of the salicylate must be continued without interruption, because a relapse may occur, and because the rheumatism has assumed a very serious phase.

M. Huchard says that rheumatism rarely provokes albuminuria, but if it occurs during the course of an acute attack of the disease, it is not a contraindication of the employment of the salicylate. If, however, albuminuria precedes an acute attack, when it is due to a renal lesion, to nephritis compromising more or less the permeability of the organ, then the salicylate is contraindicated. It may be given also to pregnant women, although in these cases one must proceed with great prudence, and give smaller doses, carefully watching the action of the medicine.

Sodium salicylate may be given in solution or in capsules of fifteen grains each, which must be carefully taken in a certain quantity of liquid, for example, in half a glass of some alkaline water; for sodium salicylate irritates the mucous membrane with which it comes in contact. It should then be diluted as much as possible, and never taken in a concentrated solution. In cases when it is not well tolerated, a milk diet should be prescribed, as it increases diuresis and insures better elimination of the medicament. M. Huchard has often found it well to associate this remedy with sodium bicarbonate, giving them in alternate doses every two hours. The salicylate should be taken during meals or in milk. In particular manifestations of rheumatism, the salicylate has only a very doubtful action, if it has any at all.

The Etiology of so-called Scurvy-rickets.—The December number of the Practitioner contains an article on this subject by Dr. Henry Ashby, of Manchester, who, referring to Dr. Cheadle's and Dr. Barlow's views that the anemic and hemorrhagic condition sometimes seen in rickets is the result of the absence of fresh food, and is true scurvy, says that he thinks the presence of true scurvy has certainly not been proved in these cases, that, in some cases at least, there has been no deprivation of fresh food, and that there is much to be said in favor of the view that there is a close connection between this hemorrhagic condition and acute rickets. Some infants, he says, between the ages of six months and two years, who have perhaps suffered much from bronchitis, who have been fed on anything but an ideal diet, are very anemic, with rickety boses on the ribs, and the chest falling in with every respiration, while the epiphyses of the long bones are more or less tender. Perhaps, after a few days the urine is colored, and it is evident that blood is oozing from the capillaries of the kidneys or the bladder. Or there may be evidence of bleeding beneath the periosteum or elsewhere. The question naturally arises, Where does rickets and scurvy begin? Why, says Dr. Ashby, assume the presence of a new disease when a tendency to bleed is added to anemia? Does not the same thing happen in other diseases? In tuberculosis in children there is often marked anemia with a tendency to bleed from the gums and from other parts, although there has been no absence of fresh food of any kind.

There seems to be a doubt, says the author, that scurvy is to be considered as a disease which is brought on by the absence of fresh vegetables or by the absence of fresh food generally. Fresh vegetables are looked upon as preventive of scurvy, but with regard to fresh food, such as meat and milk, there is no such agreement. An absence of fresh vegetables from the dietary of an infant can hardly cause scurvy, for during the first year neither grapes, oranges, potatoes, nor watercresses find any place in it. While it is true that in some of the reported cases of so-called scurvy-rickets there is a history of almost exclusive feeding on preserved foods, yet it is so by no means always the case; in some of the author's cases fresh milk, raw-meat juice, and potatoes entered into the diet.

In the cases of scurvy collected by Dr. Sutherland, says the author, there is an overwhelming proportion occurring between the seventh month and the twenty-fourth; in his own cases all the patients were between these ages, and this, he thinks, can hardly be accidental, but points to a close association with rickets.

The fact that recovery takes place more or less quickly after antiscorbute treatment has been begun is one of the strongest points in favor of the scurvy theory. In some, undoubtedly, improvement begins quickly after suitable treatment has been begun. Milk, cream, or whey, according to the capabilities of the child, raw-beef juice, orange juice, and emulsion of cod-liver oil, with as much fresh air and sunlight as possible, constituted the treatment in Dr. Ashby's cases. In the worst cases improvement was slow, and in several others fresh bleedings made their appearance after the treatment was begun. The author thinks that fresh air is just as important as fresh orange juice, and that fat in some form or other, if it can be digested and absorbed, is also of the highest importance. There can not be much doubt that a long-continued use of any one food, breast milk alone excepted, is bad, especially if that food is poor in fat. Carbohydrates can not take the place of fat permanently. Sterilized milk, if it has been long heated, especially at the high temperature of from 215° to 221° F., is apt to be injured as a food in consequence of the separation of the fat. Pancreatized milk or malted milk is good as a substitute, but it is not safe if it is to form the sole food for months together.

Dr. Ashby thinks that it would be wise to drop the word scurvy altogether in connection with these cases, and to speak of them as rickets with a hemorrhagic diathesis. That there is a close association between the two conditions, he says, few will deny, but what that association is it is impossible to say. So little is known about the pathology of rickets, and so much has yet to be learned about its etiology and the links which connect the dyspepsia and bad feeding with the changes which take place in the bones, viscera, nervous system, and blood, that we are hardly in a position to form hypotheses. There can be no doubt, says the author, that indigestion and improper food are largely responsible for rickets, and are thus more or less
directly concerned in the hemorrhagic diathesis which supervenes in some cases. If the word scurvy is to be retained for such cases, we must enlarge its ordinary signification.

**Strontium Salicylate.**—Dr. II. C. Wood, of Philadelphia, contributes an article on this subject to the *University Medical Magazine* for January, 1895, in which he says that for some years he has been trying to find a way of obtaining the general action of the salicylates without gastric disturbance. At one time, he says, most of his patients received oil of gaultheria, which in many cases is less disturbing to the gastric mucous membrane than salicylic acid or sodium salicylate. Subsequently, however, he found that ammonium salicylate, given in milk, was usually much better borne than the oil of gaultheria. Dr. Wood's clinical experiments closely accord with Laborde's statements that the haloid strontium salts agree with the human digestive apparatus very much better than the corresponding salts of sodium and potassium, and it occurred to him that the strontium might be able to overcome the disagreeable effects of salicylic acid. When given intravenously to a dog, in a fatal dose, it produces death by affecting the respiration, followed almost at once by an extraordinary post-mortem rigidity. In some instances there was vomiting, but never purging. In order to determine whether it had any distinct depressing influence on the circulation, the following experiments were made with sodium and with ammonium salicylate: 1. A six-per-cent. solution of sodium salicylate was administered to a dog weighing 28½ kilograms. The arterial pressure was not distinctly affected by the intravenous injection of a hundred cubic centimetres; after forty cubic centimetres more were given there was a rise of ten millimetres in the arterial pressure, which was maintained for between one and two minutes, when under the influence of another twenty cubic centimetres the pressure began to fall slowly. Again twenty cubic centimetres were given and the rate of fall was increased. When the arterial pressure had decreased from a hundred and eighty to fifty-two millimetres, the respiration ceased; the heart continued to beat for half a minute longer. 2. A six-per-cent. solution of ammonium salicylate was injected into a dog weighing 21½ kilograms. The rapid injection of twenty cubic centimetres of the solution into the jugular was followed by a pronounced immediate fall of pressure, and a few seconds later by a rise. After repeated injections until eighty cubic centimetres had been given, the pressure rose to twenty millimetres above the normal. This rise was increased sixteen millimetres by the gradual injection of eighty cubic centimetres more. Then a very slow injection of forty cubic centimetres more was administered, after which violent tetanus developed, and the arterial pressure rose to fifty-six millimetres above the normal, falling rapidly half a minute later, when the muscles relaxed, during rest, to a hundred and twelve millimetres below the normal. Ten seconds after this the respiration ceased, the heart continued to beat for twenty seconds, and the arterial pressure gradually descended to zero. 3. In this experiment a six-per-cent. solution of strontium salicylate was used. After the injection of a hundred and fifty cubic centimetres the blood-pressure was still above the normal, although a few seconds later an additional injection of ten cubic centimetres was followed by a rapid fall of the pressure, ending in death by respiratory arrest. The heart continued to beat distinctly for twenty seconds after respiration had stopped. In other words, eleven cubic centimetres to the kilogramme of a six-per-cent. solution of strontium salicylate, intravenously injected in broken doses for a length of time, did not produce any immediate fall of pressure.

Contrasting these results, says Dr. Wood, with those obtained from the use of the sodium and the ammonium salicylates, it will be seen that the dose of strontium salicylate necessary to lower arterial pressure was nearly twice that of the sodium salicylate, and distinctly more than that of the ammonium salicylate.

With the knowledge acquired from these results, says Dr. Wood, it seems entirely safe to use the strontium salicylate in the human subject, and he has accordingly employed it in a large number of cases in doses ranging from fifteen to a hundred and twenty grains a day. The result of these trials shows that in doses of from five to ten grains, given after meals, the salt very commonly improves digestion, and the dose of five grains an hour after meals, in flatulent dyspepsia and in various conditions of tendency to fermentative changes in the alimentary canal, is a useful intestinal antiseptic, one that has seemed to the author to give better results than salol, naphthol, or any of the older intestinal antiseptic remedies. It does not produce cinchonism so readily as the older salicylates, but it may produce a pronounced degree of cinchonism. The author has not tested it in acute articular rheumatism, but thinks it would be less efficacious than the ammonium salicylate. In muscular or subacute rheumatism, as well as in chronic gouty conditions with a tendency to digestive disturbance, Dr. Wood has found it to be a very valuable remedy, exerting the action of the salicylate upon the diathesis, and improving instead of injuring the digestion. It may be given in solution, but it is best administered in capsules; a five-grain capsule is of moderate size, and of these two or more may be taken at once. The taste of this salt is similar to that of the ordinary salicylates, but distinctly less offensive, so that, if it is preferred, it may be given in a weak solution.

**Ichthyl in Eczema.**—The *Lancet* for December 22d publishes an account of a case which had come under the observation of J. K. Tomory, M.B., of Edinburgh. About three years before the author saw the patient she had an eczematous eruption on the back of the neck, which gradually spread to the scalp. The hair was cut short, and a physician consulted, who prescribed an ointment and Fowler's solution. From that time she had never been entirely free from the eruption, although at times, especially when she was pregnant, it was less troublesome than at others. The eczema was very much worse in the spring. In July she consulted the author, who prescribed one application of a starch-and-boric-acid poultice, to be followed by an ointment containing an ounce of ointment of oleate of zinc, half an ounce of ointment of oleate of mercury (twenty per cent.), and six ounces of boric-acid ointment. The following mixture was also prescribed: An ounce of the compound syrup of hypophosphites, forty-eight minims of Fowler's solution, and eight ounces of water; half an ounce of this to be taken after eating. The ointment allayed the itching, but otherwise did not improve her condition. In September the author resolved to try ichthyl and gave the patient the following instructions: The head and neck were to be well washed with soft soap in order to remove any ointment that might remain, and at night a starch poultice was to be applied. The next morning the ichthyl was to be applied, and it was to be renewed once a day. Before every application the hair was to be well brushed. There was absolutely no other treatment given, says the author, and by the end of a month the skin on the neck was quite normal, and only one or two small spots could be seen on the head. By November 10th she was absolutely free from all traces of eczema, and has continued so ever since.

Mr. Tomory says he has had considerable experience in the treatment of eczema, but has never had so intractable a case. Usually he has been able to check it by means of the following lotion: Two ounces of oxide of zinc, an ounce of boric acid,
half an ounce of subnitrate of bismuth, and twelve ounces of olive oil. Arsenic is used internally when the inflammatory symptoms have subsided.

The Straining and Overtaxing of the Heart in Athletic Exercises.—The *Médecin médical* for December 19th contains a report of a recent meeting of the *Académie de médecine* at which M. Teissier, of Lyons, read a paper on this subject. On examining ten runners who had reached the goal, he says, the apex of the heart appeared to have deviated to the right [a report in another journal says to the left] from two to three centimetres; in one man, affected with aortic insufficiency, who came in second without fatigue, the apex was lowered, and, as a consequence of this deviation, the base remaining fixed, a notable increase of the precordial dullness was observed. This increase was evidently connected with a dilatation of the right cavities, as was shown by the deviation of the apex and by the results of auscultation. The cardiographic outlines collected showed the brevity of the systole and its sharpness; the characteristics of the beating of the forced heart described by M. Pitres were found.

Among all the men the arterial pressure was lowered at least six centimetres. The mechanism of this phenomenon, says M. Teissier, seems to relate to overtaxing, to general fatigue, and to secured toxic products. There is a certain degree of muscular overexcitability which appears to be due to toxic products accumulated in the blood. There is a slight but constant diminution of faradic excitability and an increase of galvanic contractility; the patellar reflex always disappears. In two thirds of the subjects examined there was appreciable albuminuria with an increase of the proportion of albumin. These results, says M. Teissier, seem to establish the fact that athletic exercises are not free from danger when carried to an extreme.

The Treatment of Traumatic Peripheral Neuritis.—At a recent meeting of the *Académie de médecine*, a report of which is published in the *Presse médicale* for December 22d, M. Delorme presented the following treatment for neuritis:

The electriax is seized between the thumb and forefinger and pressed with great force for several seconds; an interval of a few minutes is then allowed to pass, and the pressure is again applied. Generally one application is sufficient; but in obstinate cases the pressure has to be applied two or three times at intervals of from three to four days.

The results obtained from the application of a method so simple and so easy are said to be excellent. M. Delorme cited eight cases which had come under his observation in which there had been complete recovery.

Diluted Hydrobromic Acid.—The January number of the *American Journal of Pharmacy* contains an article by Charles H. La Wall, Ph.G., on the purity of this acid. Diluted hydrobromic acid, he says, is one of the articles of the Pharmacopoeia for which there is no official process of manufacture, although the standard of purity is fixed by the Pharmacopoeia in the same way as that of the other acids. While diluted hydrobromic acid is not an article of everyday mention in prescriptions, the standard of its purity should be as vigorously upheld as that of the acids more frequently used.

Some time ago the writer had occasion to examine a sample of diluted hydrobromic acid which was known to have been made by Fothergill's process. The results of the examination, he says, were so widely at variance with the requirements of the Pharmacopoeia that other samples were procured from various sources in order to ascertain the purity of the article as commonly found in the market. Six samples were carefully examined, all but one of which came from wholesale and manufacturing houses in Philadelphia, and not one of the samples tested fulfilled all the requirements of the Pharmacopoeia, and, while one or two approximated a state of purity, the remaining specimens were quite impure and showed evidence of very careless or faulty methods of manufacture. Free salicyluric acid was present in several of the samples, an inexcusable contamination, says Mr. La Wall, and all of them indicated a higher percentage of absolute hydrobromic acid than is allowed by the Pharmacopoeia.

The Effect of Massage on the Circulation.—The *Journal of Physiology* for December 15th publishes an article on this subject by Dr. T. Launder Brunton and Dr. F. W. Tunnell, which, after giving a detailed account of their experiments, sums up the results as follows:

1. During the massage of muscles the flow of blood through them is increased.
2. Immediately after the cessation of massage, an accumulation of blood occurs in the massaged muscles, which is rapidly followed by an increased flow through the muscles.
3. The massage of a considerable muscular area causes at first a slight rise in the general blood pressure, which is followed by a fall in that some cases amounts to a fifth of the initial blood pressure.

The Disposal of Garbage in New York.—The following resolutions, adopted by the Section in Public Health, Legal Medicine, and Medical and Vital Statistics of the New York Academy of Medicine, were approved by the academy on January 3d:

*Whereas,* In many cities garbage is disposed of by garbage furnaces within the city limits, without odor, smoke, or nuisance of any kind whatever, as well as at a profit; and

*Whereas,* In New York the disposal of garbage by seows entails a complete loss of $175,000 per annum, and causes an intolerable nuisance to the dwellers on the neighboring coasts because of garbage, ashes, and carrion floating ashore, which substances may, by means of garbage furnaces, be transmuted into steam power that would have a value of $160,000 a year; therefore be it

*Resolved,* That the present cumbersome, expensive, and insanitary system of collecting, transporting, and disposing of the household garbage of New York should be abolished.

*Resolved,* That the city be divided into districts, and that the privilege of collecting and disposing of garbage be sold to contractors, held under bonds for the faithful performance of their duty.

*Resolved,* That it be recommended that coal ashes be collected and stored by householders without swill admixture, as is at present required by law.

*Resolved,* That odorless garbage furnaces be constructed in each district, as in other cities, and that all garbage be disposed of immediately by incineration therein, while the ashes and junk be disposed of by the contractor as a source of profit.

*Resolved,* That, inasmuch as at the present time the sanitation of households in New York is under the supervision of the board of health, it be recommended that the collection and disposition of the household garbage be committed to that department and divorced altogether from that of street-cleaning.

*Resolved,* That this reform is recommended in the interest of public economy, as the present system in vogue is unsatisfactory and expensive; besides, by establishing modern scientific discoveries and principles, what is now a matter of great expense may be made a source of revenue to the city.

THE ARTHROPATHIES OF LOMOMOTOR ATAXIA.*
By PARKER SYMS, M. D.

In the issue of July 7, 1888, of the New York Medical Journal I published a paper on Arthropathia Tabidorum. My excuse for addressing you now on this subject is my desire to emphasize some points of importance, to state the results of my continued study of the disease, and because I believe this theme to be one of particular interest to the general practitioner, and yet one concerning which very little has been written.

The study of structural diseases of joints depending upon central and peripheral nerve lesions is of comparatively recent date. As progress has been made in this direction it has been found that a number of diseases of the nervous system may be responsible for grave arthropathies. These nerve lesions are usually those which belong to the degenerative variety, in which the essential tissues of the nerve centers or trunks are so altered as to no longer be proper nerve tissue, or in which there is absolute destruction or loss of the nerve structure. Among this class those diseases which involve the posterior portion of the spinal cord, affecting sensation and circulatory conditions, are the ones which are particularly responsible for the joint diseases. Principal among them are locomotor ataxia and the condition known as syringomyelia.

Syringomyelia is a condition in which there are clefts or cavities in the substance of the spinal cord. These clefts may be congenital or may be the results of degenerative disease. In the latter case the disease consists of three stages: (1) The spinal cord is infiltrated with round cells and connective-tissue nuclei; (2) the replacement of the medullary elements by a feltlike connective-tissue increase or gliomatosus mass; (3) this has a tendency to break down in its center, leaving cavities lined with this feltlike connective tissue. These cavities usually contain clear serum, sometimes bloody or hyaline material.

Locomotor ataxia consists pathologically in degeneration of the posterior columns of the spinal cord, apparently extending from the center outward; it finally involves the posterior nerve roots, often the lateral columns, and, as has been shown by careful investigators, the nerve trunks and terminals are also involved. The degeneration consists in atrophy and loss of the essential nerve tissue, accompanied by an increase of connective tissue and a deposit of fat.

That these and similar diseases do cause very grave and remarkable arthropathies is well known, and yet the exact relation of the spinal lesion to the joint trouble does not seem to be clear, and many opposed opinions and theories have been advanced.

The study of the aetiology of the arthropathies of loco-

motor ataxia needs first the study of the parent disease and subsequently a study of the joint trouble.

The causes of locomotor ataxia are certainly not known and are only surmised. All that can be said is that it is more common among men than among women; that it is a disease of middle and advanced life. In a very large percentage of cases the patients have had syphilis. In the majority of cases one can obtain a history of excessive venery, of excessive brain and nerve tax, or excess in the use of alcohol. Often the onset is charged to some severe crisis involving exposure to wet and cold combined with physical exhaustion. There has been a great deal of dispute concerning the relation of syphilis to tabes dorsalis. I believe the majority of authors regard syphilis as the cause of locomotor ataxia—i.e., that the disease occurs as the direct result of syphilis, and never in patients who have not been so infected. A few regard a previous history of syphilis as merely a coincidence and not as a cause, while some regard syphilis as one of several predisposing causes of the spinal lesion. My own conviction, based on the study of a sufficient number of joint cases, is that locomotor ataxia may occur independently of syphilis; that any prolonged and destructive tax upon the nervous system may so exhaust it that the circulatory conditions shall become unbalanced and the nutrition of the cells so altered as to result in degeneration of the nerve substance. Excess of venery, of prolonged intense nerve work, prolonged deprivation of sleep, rest, and nutrition, excess in the use of alcohol and in the exercise of nerve energy under stimulation, all diminish the opportunity for physiological rest and for cell repair. Any grave disease, as tuberculosis or syphilis, also taxes the system and not only may, but certainly does, act as a factor in the production of disease of the nerve centers. Certainly, if syphilis is necessary for the production of tabes dorsalis, there can be no case without it; but in a large number of tabetics one can neither obtain a history of syphilis nor can he demonstrate any syphilitic lesion. Syphilis is unfortunately a very evident disease, and the cases which are severe enough to be the cause of locomotor ataxia may reasonably be expected to leave some impression on the patient's mind, if not upon his body. Certainly it is but surmise to allege that syphilis has been found in a patient when no evidence of the disease exists and none can be recalled. It must be conceded that excess of venery is a predisposing cause of syphilis. Perhaps the excess which made the syphilitic infection possible may also have damaged the nervous system by exhausting and overtaxing its powers of repair.

Concerning the aetiology of the joint lesions in locomotor ataxia, I take the liberty of quoting from my former paper. It has been maintained:

1. That it is purely a mechanical condition caused by the abnormal gait of the patient, due to locomotor ataxia.
2. That it is due to a direct trophic disturbance of central origin—a certain point being involved for a corresponding joint, or that there is one center responsible for the nutrition of joints. (Buzard suggests that this hypothetical point is in the medulla.)
3. That it is not a peculiar disease, but is (a) arthritis deformans coincident with the tabs, or (b) a purely syphilitic joint in the same connection.

4. That the serous effusion is due to trophic disturbance, and that the changes in the bone are due entirely to the pressure of the effusion and the consequent anemia of the periosteum. (Maenamar.)

5. That it is due entirely to a traumatism and that the primary changes are inflammatory, but, owing to analgesia, the joint is not kept at rest and progress is different, merely on that account, from ordinary traumatic arthritis.

6. That it is due to a direct trophic disturbance, like ulcus perforans, not of central origin, but due to atrophy of the peripheral nerves (Weizsächer). I understand this to mean that only the nerves of the diseased joint were atrophied, and therefore this joint became involved.

7. That it is due to traumatism or some change in the condition of the joint to be affected. The progress attained depends on the fact that the nerves of all large joints are degenerated, and some degeneration occurs in the structures of apparently healthy joints in tabetic, as pointed out by Jurgens and Westphal.

I am inclined to the last theory. The fact that the nerves and structures of seemingly healthy joints are in a state of partial degeneration has been demonstrated, and it only remains to assign a reason why a certain joint should continue in the process. I think it is reasonable to look for this in some local condition, such as traumatism. If it were simply a continuation of the degenerative process, other joints would be involved in time. But a patient may have a single joint affected for years.

The idea that it is dependent on the peculiar gait is not tenable, for the disease occurs before incon-ordination is present, and patients have developed it while lying in bed; also because it occurs in the upper extremity.

Neurologists have not found for us the central point alleged by Buzzard and Charcot, and changes in the peripheral nerves seem to explain the disease more satisfactorily. Charcot’s disease differs in its pathology and symptoms from arthritis deformans and syphilitic joints sufficiently to give it an identity as a peculiar condition.

The idea that it is caused by the serous effusion, as suggested by Maenamar, it seems to me does not need contradiction.

I do not consider it of a purely traumatic nature. The changes are none of them of an inflammatory nature, and certainly must be regarded as due to nerve changes.

The pathological changes in these joints are remarkable, involving both the bone and the soft parts, producing the most extreme deformities. The synovial membrane is usually anemic, though sometimes congested. The capsule becomes very much thickened by connective-tissue increase. The circumarticular structures are often the seat of extensive connective-tissue hyperplasia, and this mass forms a large part of the deformity. The entire capsule may be destroyed and be replaced by a mass of new connective tissue. There is always a hydrarthrosis early, and a peculiar effusion into the deep fascia and the soft parts, sometimes extending throughout the limb. The capsule and ligaments are stretched and distended by the swelling and hydrops. This gives an abnormal mobility to the joint. Ossification occurs in any of the tissues at and about the joint. Bone formations may be found in the tendons, muscles, fascia, and capsules, or they may be formed as free bodies in the joint cavity. There are two classes of cases, owing to two sets of processes which occur in the bone tissue—viz., the hypertrophic and the atrophic. We may find a joint dis- eased in both manners—that is to say, one bone of the joint may be hypertrophied and the other atrophied. In the atrophic form the ends of the bone and the epiphyses are more or less absorbed, and the bone may terminate in a rounded end like a drumstick.

The hypertrophic form produces great increase in the size of the bone by large bony deposits and outgrowths on the epiphyses. These bony deposits are not confined to the epiphyses, but also involve the shaft, and are often found on the capsular and soft parts. Spontaneous fractures are very common. They may involve the shafts or the processes. These fractures may unite, often forming good union, but the callus is usually overabundant. The bone structure is changed microscopically and chemically. As in osteitis rariﬁens, the lamellae are absorbed and broken down so that several canaliculi are transformed into one large canal. The bone plates are thinned, and the canals are ﬁlled with fat. As in osteomalacia, the phosphates are diminished to about eleven per cent., and the fat is increased to about thirty-seven per cent.

In the hypertrophic forms the joint functions are usually better than in the atrophic. In the latter the opposing surfaces are diminished, and the lack of support allows great freedom of abnormal motions.

The symptoms are well marked, and the disease is easily recognized. As these joint affections come early in the course of locomotor ataxia, we may not have many symptoms of that disease present to aid our diagnosis; but we are sure to ﬁnd some. The prominent symptoms of tabs are darting neuralgic pains, numbness and peculiar sensations in the front and legs, perverted response to surface irritation, as an exaggerated sensation of cold applied to the skin, or the application of cold may produce a sensation of heat, etc. Tactile sensation is often delayed. Analgesia is a prominent early symptom of tabs, and is a constant condition. So is loss of patellar reﬂex. The Argyll-Robertson pupil is one of the characteristics of the disease. Inco-ordination of the muscles of the extremities is very prominent as a symptom, but it comes on late in the disease. Owing to the blunted sensation in the feet there is more or less inability on the part of the patient to walk or stand steadily without the aid of sight, and in the dark, or with the eyes closed, he will sway and stagger. Inability to walk at night and the peculiar sense of numbness are usually the ﬁrst warnings to the patient of this disease of the spinal system.

The joint disease is characterized by its sudden onset and comparative absence of pain. Sometimes the ﬁrst indication of the disease is a spontaneous fracture of a bone shaft, but usually there is a sudden and rapid swelling of the limb produced by an edema of the deeper parts.
This general swelling subsides, but the joint is found to be deformed, and remains enlarged. The peculiar deformity of the joint, its rapid development, the absence of pain, attended by some of the characteristic symptoms of locomotor ataxia, complete the means of diagnosis. It may be mistaken for arthritis deformans, but this latter disease comes on slowly, is attended by severe pain, and you will be aided in differentiating by the absence of the symptoms of tabs. Besides, in arthritis deformans the motion of the joint is restricted, while in arthropathia tabidorum the joint is usually abnormally movable.

In these cases the disability is great, especially late in the spinal disease when inco-ordination is added; but I have never seen a patient who could not walk with the aid of crutches or a cane. One of my cases has improved in his ability to walk owing to the fact that his knee, the seat of the disease, has become ankylosed, and, though still greatly deformed, it is strong and gives him firm support. Six years ago, when I first saw him, mobility was so great that he walked with much difficulty. Knowing that in these cases fractures would unite, I was of the opinion that resection of the knee in this case would be justifiable, and that he would be much improved by the operation. Nature has accomplished all that I could have hoped to do by operating, and I now know that I might have failed in my object.

This week I saw a case of this disease in a knee joint in which resection had been done seven years ago by Dr. Willy Meyer, of this city. The final result shows that union of the bones had failed to take place; and, while the man can walk with a cane, the joint is not better than the average of these cases in which no operation has been done. As I am ignorant of the man’s original condition I am unable to state whether the operation was an advantage or not.

Beyond the use of splints in those cases where mobility is great, very little can be done in the way of treatment. The disease is permanent, and the patient I have referred to is the only one of my acquaintance who has improved. Further experience may show that resection is advisable. Notwithstanding the case above referred to, I am still of the opinion that we may expect union to take place after resection. If this is true, the operation would often afford great relief.

I have had no reason to change my conclusions as expressed six years ago. They are as follows: (1) That this is a peculiar disease depending on tabs dorsalis; (2) that it is due to trophic disturbance; (3) that it is of the nature of a degeneration, and not of an inflammation; (4) that syphilis is not a necessary factor of locomotor ataxia; (5) that in some cases excision of the diseased joint may be justifiable.

The following is the history of two typical cases which I take pleasure in showing you:

Case I.—Henry B., sixty-two years of age, a sea cook by occupation. No history of syphilis and no evidence of syphilis. When six years of age was kicked by a horse, probably receiving a fracture of the right parietal bone. He says he was unconscious for six days, and that he bled a good deal; does not know if from ear or nose. There was no resulting paralysis of speech or motion. Since this accident he has been deaf in the right ear. His subsequent history is negative till 1883. At that time, after taking a bath and exposing himself to cold, he suddenly developed what he calls a weakness in his legs. Hs gait was unsteady, and he was thought to be intoxicated. Soon he lost to a marked degree the natural sensation in his legs and feet; they felt numb and as though he walked on an uneven, spongy surface. His symptoms have always been more marked on the left than on the right side. There was very little change in his condition till about the middle of the year 1887. At that time his knee swelled to more than its present size within a week. It attained its present deformity within a month. The joint was very movable in all directions. When he stood it took a position of extreme adduction. When I first saw him, in the latter part of 1887, there was a peculiar hard swelling of the entire limb. There was a large, imperfectly movable mass below the middle of the thigh. This later became reduced in size, and ossified on the shaft of the femur. Examination five months after the attack of general swelling of the thigh showed anaesthesia, deep and superficial, of both limbs; sensation not delayed; patellar reflex absent; pupils do not respond to light; patient sways when standing or walking with closed eyes; left knee very much enlarged and deformed, measuring ten centimetres more than the right knee. There was some increase in the size of the entire limb; there was fluid in the joint cavity, marked crepitus on motion; lateral mobility greatly increased; general contour of joint lost, owing to thickening of the capsule; internal capsule greatly hypertrophied. There was also a spine of bone, ten centimetres long, on the inner side of the lower end of the shaft of the femur.

Examination on October 8, 1894, showed the left knee joint very much enlarged and deformed, measuring ten centimetres more than the right knee, over the patella; the knee was ankylosed; the position of leg was not one of normal extension, but adduction, causing a marked bow. Owing to the ankylosis, the limb gave a firm support, and the patient was able to walk quite well.

Case II.—Laura H., admitted to the Colored Hospital on March 21, 1894; fifty-four years of age. Evidence of old syphilis, but no history of the same. The present illness began
in the early part of 1892, with numbness in both feet. In the
fall of 1892 she began to have shooting pains in calves of legs.
About December, 1892, her right knee became swollen and
caued her some pain. There were present the Argyll-Robertson
pupil and loss of patellar reflex; sensation in the legs was
delayed, and was also diminished; she swayed when standing
with closed eyes. The right knee was greatly deformed and
enlarged; the patella was firmly fixed to the femur; the lower

end of the femur was greatly hypertrophied, especially at the
inner condyle. The ligaments and capsule were much dis-
tended and stretched. The upper end of the tibia was some-
what atrophied, and was subluxated backward and outward.
There was flexion to more than ninety degrees; extension to
more than a straight line; abduction to about a right angle;
adduction to about forty-five degrees. The right knee meas-
ured seven centimetres more than the left at the greatest cir-

Purpose Condition.—Well-marked enlargement of either lobe
of the thyroid gland, excessive enlargement of both tonsils,
which were subluxed with closely packed papillary bodies, and,
as a consequence, difficulty in swallowing; deafness, alteration
in the voice, and also in the expression.

The tonsils literally filled the throat. One could scarcely
believe that any food could be forced past them, so large were
they, and so completely did they obstruct the faucies. They
were rough and ragged in appearance at first glance. On closer
inspection, however, the rough appearance was seen to be made
up of numberless papilla or pedunculated masses, packed closely
together and extending downward as far as one could see or
feel with the finger. They also bulged so far forward as to
hide the uvula completely and rest on the base of the tongue.
There was very little sensation in them, and, bulging as far for-
ward as they did, there was no difficulty in palpating them.
Each papilla seemed to have a separate and distinct entity.
Some had a very small pedicle, others larger, but none sessile.
So large and so closely packed were these papilla that one could
not help wondering at her being able to swallow at all. While
she could swallow fluids if taken very slowly, there was always
difficulty in the deglutition of solids. The solid particles ap-
peared to get tangled up in the papilla and would only pass on
down after repeated efforts at swallowing. With such masses
in her throat it is not to be wondered at that there was some
difficulty in hearing and speaking. The change in her facial
expression was, I suppose, due to her deafness and constantly
keeping her mouth open.

The tonsils were so utterly unlike anything I ever saw be-
fore that I delayed doing anything whatever for her in order
to allow all the members of the staff and several other medical
friends to see her at their leisure. The size, as well as the ap-
appearance, was something unique. In fact, the case was a "rara
acina" to each and every one of us who saw her.

That a better idea of the size and appearance of the tonsils
might be formed, I asked the photographer to the hospital (a
professional) to photograph them. He made a number of at-
ttempts to do so, both at the hospital and at his studio, but with-
out any success whatever. Knowing that our former president,
Dr. Powell, was very much interested in amateur photography,
and knowing also that amateurs in photography, as in every-
thing else, like to get hold of something which is considered
"difficult" by ordinary mortals, I asked him if he would try
to secure a view of her tonsils. After a great deal of trouble
and several "sittings" he managed, with the aid of the mag-
nesium flash light, to get a photograph of the upper and an-
terior surfaces of the tonsils. This I now show you. Your
imagination will enable you to form an idea of what the whole
size and appearance must have been.

Shortly after Dr. Powell's getting the photograph of the
tonsils and before any treatment was adopted, the patient was
taken ill and died within forty-eight hours. Both scarlatina
and diphtheria had been introduced into the hospital a few
weeks before this by children or friends coming to visit the
little patients, and several cases of each disease had been sent up to the isolation wards a few days before this.

Almost the earliest symptom she complained of was "sore throat." As soon as seen by the house physician her throat was examined, and all the papillary growths and the few intervening spaces were seen to be acutely inflamed and covered with a grayish-white membrane very suggestive of diphtheria. The membrane, though, looked thinner than the typical diphtheritic membrane even in its initial stage, and yet it could not be peeled off without using undue force. The uvula could not be seen, neither could the pillars of the fauces nor the soft palate, all being hidden by the tonsillar outgrowths. The discomfort and pain in swallowing were increased. The disease was not ushered in by a chill, a convolution, or by vomiting. There was no rash. The submaxillary and cervical glands were somewhat enlarged and tender to the touch. Her temperature ran up to 102.5° and the pulse was increased to 120 to 130. The countenance was in indicative of serious illness. The patient looked more seriously ill than is usual with follicular inflammation of the tonsils; besides, one glance at the tonsils and the uniform and complete character of the membrane showed us that we had to do with something more than follicular tonsillitis.

At this early stage the diagnosis lay between diphtheria and scarlatina, with a leaning toward the former. Both diseases had found their way into the ward occupied by the patient. As the mother lived out of the city we could not consult her as to whether the patient had ever had scarlatina. It was necessarily a case of waiting for more data on which to form a diagnosis.

I also show you the tonsil itself, very much shrunken, of course, from its immersion in alcohol for more than two years.

Dr. John Caven has examined a portion of the tonsil microscopically and reports as follows:

Microscopic examination of the tissue shows it to be lympho-adenoil in nature. Unfortunately, improper hardening and preservation has so deteriorated the structure as to render sections very unsatisfactory. However, it is really a true hyper trophy of tonsil, tonsilar tissue being reproduced. Whether congenital or not I can not determine. I have not been able to find a reference to an exactly similar condition in any work; the nearest to it is a papillomatous condition of the mucosa of the pharynx resulting from chronic pharyngitis. I would compare it with post-nasal adenoids.

J. C.

My first impression on seeing the tonsils when she entered the hospital was that it would be a good case for the use of the amyladalatone, but I think now, from the case with which I enucleated the one, that in similar conditions, or in cases of very large tonsils, enucleation would be preferable and probably quicker. There was no difficulty in shell ing it out with the forefinger and finger-nail, and I was a very little longer time in doing it than is ordinarily taken in performing amyladalatony. In enucleation, one could be certain that the stump would give no future trouble—a result which can not always be promised after amyladalotomy.

The Jarvis snare might have been used, and from the large size of the tonsils and the consequent dililency in getting the tonsils in the ring of the amyladalatone, I think the snare would probably have answered the purpose better than the ordinary amyladalatone. Even with the largest-sized amyladalatone, and taking ample time over it, I am positive the whole of the tonsil and its outgrowths could not have been drawn through the ring. Therefore it would have been necessary to introduce the amyladalatone two or
probably three times before getting away the whole of it. In this way longer time would have been consumed than with enucleation.

That these papillomatous tumors of the tonsils are very rare I am convinced from a careful search of all the modern works on pathology at present in our library here. They are not even spoken of in any one of them; nor is there any mention made of them in any of the works devoted especially to diseases of the throat. What is yet more surprising, no reference is made to such a condition in the Index-Catalogue of the Library of the Surgeon General’s Office of the United States Army, a work which contains a reference to almost everything published for half a century past.

Some of the interesting points in connection with this patient—
1. The presence of a lipoma of the neck at four years of age and its difficult removal.
2. Goitre at seven years.
3. Papilloma of the tonsils first noticed when she was eight years old—that is, at least two years before entering the hospital. Thus showing their slow growth.
4. The difficulty experienced in photographing the tonsils.
5. The impossibility of making a diagnosis between scarlatina and diphtheria in the very early stage of her acute illness.
6. The case with which enucleation was done just after death.
7. The extreme rarity of papilloma of the tonsils.

FIVE LARGE LIVERS.

NOTES OF A SERIES OF CASES IN WHICH HYPER TROPHY OF THE LIVER WAS A PROMINENT SYMPTOM.

By ERNEST F. KING, A. M., M. D., WASHINGTON, D. C.

The following cases came under my observation at the Freedmen’s Hospital during the spring and summer of 1894:

Case I. Hyper trophy following Obstructive Jaundice due to Cancer of the Pan creas.—Peter C., a native of Ireland, fifty-eight years of age, drawing a pension for “heart disease, rheumatism, and incomplete inguinal hernia,” presented himself at my clinic October 13, 1893. General jaundice and severe pains in the right upper quadrant of the abdomen, with nausea and vomiting, were complained of. The liver was enlarged, especially the left lobe. Gall bladder was not made out. There was no ascites, and superficial veins of the abdomen were not enlarged. Urine was heavily charged with bile pigment; stools were clayey. The condition had begun about three weeks previously.

A diagnosis of catarrhal jaundice was made, and under treatment there was apparent improvement, the skin clearing somewhat, and the pain and vomiting leaving. Early in December he returned, however, with a much deeper color. Examination showed a tumor pressing against the abdominal wall above and to the right of the umbilicus, and moving freely with each respiration. The edge of the liver could be felt just above it.

Here was plainly a case of obstructive jaundice, and an operation was advised. A visit to friends in the country kept him away from the clinic until December 29th, when he said he was ready for an operation, and entered the hospital for that purpose.

Circumstances beyond my control prevented an operation before February 2d. During the month in the hospital the tumor increased in size, the jaundice became more intense, and strength less. The morning before the operation he had a stool, described by the nurse as appearing like “fine chipped beef that had grown black.” I operated at noon, removed seven hundred and twenty cubic centimetres of bile from the gall bladder by aspiration, and did a choles tenostomy with the Murphy button. The cause of the obstruction could not be made out. Much time was lost in checking the hemorrhage from the abdominal walls. The following morning there was some bronchitis, with bloody expectoration. The third day he had a bloody stool. He sank gradually, and died at 4.10 A. M., February 6th, eighty-seven hours after operation.

Necropsy showed both wounds in good condition. Stomach, gall bladder, and intestines were filled with a blood clot so soft that it would run through the fingers. A slight firmness about the head of the pancreas seemed to be the only cause for obstruction, and it required a macroscopical examination, showing carcinoma, to settle the matter. Cholestatic hemorrhage is given as the cause of death after a number of operations on record. While the jaundice in this case contraindicated an operation, there seemed to be no other means of possible relief. Weight of liver, seven pounds.

Case II. Amyloid Disease following Tuberculosis.—William B., mulatto, aged thirty-eight years, cook, entered the hospital on January 14, 1894. For two years he had been troubled with swollen feet and legs, with ascites during the second year. An enlargement of the liver had been noticed for a year. He was much emaciated. Liver extended half-way to the umbilicus. Abdomen tender. Caput meduse at navel. Urine albuminous. Lungs dull at apes. No cough nor expectoration. No history of suppuration. Syphilis denied. Fingers clubbed. He was brought to the hospital in a sinking condition, but lived nearly a month. Necropsy showed an amyloid liver weighing six pounds and a half; kidney also amyloid; lungs studded with gray tubercles.

Case III. Carcinoma.—This case has already been reported in a footnote to Dr. William Osler’s lecture on Tumors of the Liver, published in the New York Medical Journal, April 7, 1894. Dr. Osler’s note is as follows:

“A case illustrating an error in diagnosis is that of hospital number 5234, Joshua M., aged fifty-four, admitted May 16, 1892, with swelling of the abdomen and an illness of nearly a year’s duration. The patient was a large, powerfully built man; had always enjoyed good health, and denied venereal disease. For nearly a year he had had trouble in the abdomen, and had twice been slightly jaundiced. The legs had been swollen, and he had had shortness of breath. The examination showed an enormously enlarged liver. The whole of the upper part of the abdomen was filled with a hard, irregular, nodular mass, corresponding to the greatly enlarged liver. The lower border was felt midway between the umbilicus and the pubes. There were prominent bosses on the surface of the liver, and from its great size and irregularity there seemed to be no question as to the correctness of the diagnosis of secondary cancer of the organ. No primary disease could be determined, and there was decided hyperacidity of the gastric juice. The patient remained in the hospital for a month and gained slightly in weight, but the liver developed still further, and the irre-
larity on the surface was more marked. An aspirator needle was thrust in, but nothing but blood obtained. Naturally enough the diagnosis was entered as cancer of the liver. Dr. E. F. King, of Washington, under date of February 19, 1894, writes that he has Joshua M. under his care at present. He has a well-marked syphilitic skin eruption, and the liver, still enlarged, extends nearly to the pelvis. The time element in this case, I should think, definitely excludes cancer, while the syphilitic rash on the skin is suggestive in the highest degree that the whole trouble is specific."

Liver of Joshua M. Weight, twenty-nine and a quarter pounds.

Joshua M. died on the fourth day after the appearance of this note, and the necropsy proved the original diagnosis to have been correct. The cancerous mass removed weighed twenty-nine pounds and a quarter. A plaster cast may be seen at the United States Army Medical Museum.

CASE IV. Cirrhosis with Enlargement.—William B., colored, aged thirty-seven years, was admitted to the hospital after a long debauch. For years he had been a hard drinker. Jaundice marked. Epistaxis controlled with difficulty. Death in thirty-six hours after admission. Liver cirrhotic, weighing six pounds. Stomach, gall bladder, and intestines contained soft blood clots.

CASE V. Sarcoma.—James Y., colored, aged twenty-two years, admitted to the hospital May 15, 1894. Right testicle four by three inches, hard. This condition had begun in childhood.

About six weeks previous to admission pain had been felt in the abdomen and a lump noticed just below the ribs on the right side. Examination showed a marked conical eminence to the right of the middle line of the abdomen just above the umbilicus, with the edge of the liver perceptible below. A poorly defined growth could be made out in the lower left quadrant. Pain was constant but not severe. There was no rise of temperature. Bowels not obstructed. Tumor grew rapidly.

An exploratory incision was made May 29th by Dr. Robert Reyburn, and the malignancy of the growth was evident at once as the soft mass from the liver oozed through the first opening in the peritumenn. The wound was closed, and the patient lived four days. The testicle showed sarcoma, evidently the disease to which the deposits in the six-pound liver were secondary.

SUTURE OF THE TORN CERVIX UTERI IMMEDIATELY AFTER LABOR.\(^*\)

BY WILLIAM R. PRYOR, M.D.,
ASSISTANT PROFESSOR OF GYNECOLOGY IN THE NEW YORK POLYCLINIC; VISITING SURGEON, CITI HOSPITAL (GYNECOLOGICAL DIVISION); VISITING GYNECOLOGIST, ST. ELIZABETH HOSPITAL.

Severe and alarming hemorrhage from the cervix may follow from a deep cervical tear and will demand checking by suture or by ligature en masse. None will dispute that. Such a laceration of tissue takes on the characteristics of an extraperitoneal rupture of the uterus, and any operation performed to check such bleeding from the uterine artery and its branches should not strictly be called a tachelor-raphy. The separation of tissue here is important because of the hemorrhage only.

We are further to consider whether any other indication post partum may demand immediate closure of a torn cervix.

It is maintained that post-partum hemorrhage from the corpus is prone to occur with severe and fresh tears, due to lack of contractile power in the uterine muscle. A pregnant woman has an hypertrophied or rigid cervix, and, as is usual with such, a weak uterine muscle also. The first stage of her labor is tedious and the cervix is subjected to much pressure. Suddenly it yields by tearing. Post-par- tum bleeding from the fundus follows. The mere fact of a cervical tear does not produce this; but it is due to a bleeding from the cervix robbing the uterine muscle of blood, or else and more often it is the result of fatigue of the uterine muscle and paralysis of the cervical ganglia upon whose influence depends largely the contraction of the uterus. Furthermore, women who have old and very pronounced lacerations are less prone, in my experience, to post-partum hemorrhage after subsequent labors than those with intact cervixes. Their uteri have less work to do to expel their contents, and have abundant reserve strength to properly contract post partum. Again, post-partum bleeding is not a feature of labors completed by means of Dührsen's incisions, whether these are immediately closed or not. It is the hemorrhage from the uterine artery, the long-continued pressure acting upon the cervical ganglia, the over-effect on the part of the corporeal muscle which produce the post-partum hemorrhage, and not the subtle effect of any separation of cervical tissues.

Another immediate result of laceration of the cervix is said to be subinvolution. A careful analysis of all the cases of subinvolution I have met with, associated with laceration of the cervix, convinces me that this retarded involution results from other causes, more especially from the character of the labor, than from any influence of the torn cervix. Certainly in my experience it is more common to find it occurring after first labors than in women who are multiparous and who have torn cervixes.

I must ask the fellows to remember that at each uterine contraction the corpus is deprived of blood circulation. This persisting through an obstructed labor, and probably

* Read before the Society of Alumni of Bellevue Hospital, November 7, 1894.
followed by much loss of blood, are the causes predisposing to subinvolution. The causes of subinvolution are entirely apart from those of laceration of the cervix. One argument advanced is that when the cervix is torn the uterine muscle has nothing to hold on to in trying to contract. If there were no opposing sphincter cervix whatever, contraction of the corporal muscle would probably be complete, as is noticed with other involuntary muscles when the opposing structure is removed. They enter into a condition of tonic contraction. I must qualify this statement, as to a lack of influence of laceration here by excepting cases which I consider as pathological laceration.

A pathological laceration is one which implicates the internal os. This at term is but part of the lower segment of the uterus. Laceration of this point constitutes a true extraperitoneal rupture of the uterus.

The liability of an open torn cervix to become infected is a question difficult of solution. If the confinement has been, surgically, a clean one, infection can not occur. To operate in such a case is to introduce into the genital tract instruments and material which may not be clean—is to interfere with a perfectly healthy and clean surface for, perhaps I may say, sentiment.

If the accouchement has been filthy, still less right have we to look up in that uterus the lochial discharge. It is certainly the open cervices of Duhrssen's incisions do not become infected. They are clean. No such condition of gaping, everted lips eager to take up sepsis as the speculum reveals actually exists in the undisturbed relations of the parts.

A critical examination of the frozen sections of post-partum cases fails to show such separation of the torn cervical lips as those who so earnestly advocate trachelorrhaphy picture. The two forces, atmospheric pressure and intra-abdominal pressure, very sufficiently and properly bring such torn cervical lips into apposition. A carefully made vaginal examination will prove the same relation of the parts to exist. Thus it is that the immediate separation revealed by the speculum by no means measures what will ultimately result. I must confess my inability to determine exactly what parts of the structure exposed by the speculum immediately after labor shall be united by suturing. A portion of the cervical tissues has become apparently part of the vagina, and another portion has been drawn up to form part of the lower segment of the uterus.

If I had not the indication of bleeding and had to be guided solely by the appearance of the lacerated and bruised tissues for the limitations of my suturing, I should unite either too much or too little. I believe it to be utterly impossible in many cases immediately after labor to determine...
accurately how much will prove cervix when involution has become complete and how much will be lower uterine segment or vagina.

The anatomical relations are so disturbed by the merging of uterine and vaginal canals into one parturient tract that absolute definition is impossible. In some cases the limitations of tissue are perfectly plain. The confusion in structures is very well shown in the two cuts submitted.

It is the author's belief that there is but one indication for immediate repair of the torn cervix—hemorrhage.

To apply the procedure in all cases where even marked separation of the cervical lips appears to exist is to introduce into obstetrics one more interfering, meddlesome, routine operation for which there is absolutely no reason; is to add more chance for infection where already too many are presented by the aggressiveness of modern obstetrics, and, above all, it undoes what Nature at great pains and beneficently has accomplished, and which we imitate by Dührssen's incisions—viz., a provision for the free escape of the lochia. I must not be understood as stating that the large everted flaps of cervical tissue which we so often see some months after labor are natural. They are certainly abnormal, but the abnorrmity existed before the woman ever conceived, has been increased by pregnancy, and does not demand suture, but just that operation to which she should have been subjected before conception.

The objection is to suturing at the time of labor such tears as are now subjected to trachelorrhaphy some time afterward. Unquestionably to do this will put the cervix into that state in which it was before labor, and will subject the woman to the same risks from subsequent confinements as attended the first. It is far better to allow the separation of cervical tissue to remain to be dealt with later, and to do such operation upon the cervix secondarily as will render any subsequent confinement more normal. Any degree of bleeding which can not readily be controlled by iodiform-gauze pressure within the cervical canal and vagina will, of course, demand suture. But tears which appear severe immediately after labor and yet are not accompanied by hemorrhage, will, after involution has taken place, result in no more than a conservative separation. Severe lacerations usually take place in cervixes the intravaginal portions of which are much hypertrophied. Unless such tears produce a bleeding demanding a controlling sutur, it is preferable to delay the amputation or amputating trachelorrhaphy until after the puerperium. I shall certainly not suture together at the time of labor tissues which should really be removed. Inasmuch as the vascular area about the internal os has been drawn up into the lower uterine segment, the tears of labor do not often produce much bleeding. It is the lower ring of the cervical tissue which tears, and this is not commonly very vascular.

A certain slight degree of tear is physiological, just as rupture of the fourchettes is, and only this physiological nicking will occur in young mothers. But when a woman bears a child with a deformed and abnormal uterus, it is not the duty of the obstetrician to return it to its first distorted state, but to correct the abnormality in order that subsequent labors may be more nearly natural. The greater the degree of cervical hypertrophy the more the necessity for a free drainage after labor, and the indication for immediate suture is wanting.

---

**DR. ROUX AND HIS SERUM THERAPY IN FRANCE.**

**By JAMES JAY MAPES, M.D.,**

**RESIDENT PHYSICIAN, NURSERY AND CHILD'S HOSPITAL, NEW YORK.**

The serum therapy in its slow and careful presentation, although following so closely after the exaggerations and disappointments of Koch's tuberculin, has been from the very first almost conclusive. Its true value, however, and the full extent to which the benefits of this discovery will reach, can not as yet be said, from a scientific point of view, to be definitely established. Meanwhile few historical events in Europe have made a deeper impression in the popular mind than the announcement of this victory over the Klebs-Loeffler bacillus. And the two men whose names have become synonymous with it—Behring in Germany, Roux in France—are currently referred to in terms of national gratitude and enthusiasm.

That the feelings of the masses should express themselves more abundantly in France than in Germany is only natural, owing to the different temperament of the two peoples; and, as a matter of fact, the French have neglected no opportunity of showing their sense of appreciation in a most characteristic way.

About three months ago, for instance, the *Figaro*, one of the leading Paris newspapers, published an interview with Dr. Roux, in which, among other things, he expressed a regret at the limited revenue of the Pasteur Institute. As there were no other resources for preparing the serum, many pressing demands, he said, had necessarily to be refused. That same day the *Figaro* threw open its columns for a popular subscription, fixing the sum of its expectations at a hundred thousand francs (twenty thousand dollars). Before the end of two months, more than ten thousand subscribers had responded to the appeal—mothers, children, grandparents, men and women of all classes—each sending his little offering, if only a franc. The total having then exceeded five hundred thousand francs (a hundred thousand dollars), the *Figaro* closed its columns; but subscriptions have ever since been steadily pouring in. In addition to the sums of money a number of chosen horses were sent to be inoculated for the general good—ponies with pet names, coach horses, and three or four full-blooded racers well known on the turf.

Another indication of the popular sentiment can be gathered from the three great benefit performances given in Paris a few weeks ago. The first was organized by the students of the university, who were allowed to use the National Theatre of the Odéon; the second was given at the Gaîté through the efforts of the Parisian shopkeepers; while the third was volunteered by the director of the Ambigu in the name of the mothers of France. The most prominent comedians offered their services gratuitously at all three performances. The president of the
MAPES: DR. ROUX AND HIS SERUM THERAPY IN FRANCE. [N. Y. Med. Jour.]

MAPES:

These corporations cabinet. his good had of the enterprise. Only a few months ago the name of Roux was little known to the general public, except for his position as chief assistant at the Pasteur Institute, where the active work of investigation had gradually devolved upon him owing to the advanced age of his master. In the medical world he was recognized as an original and patient thinker, the author of several articles on questions of bacteriology, and especially worthy of scientific esteem for his discovery of the diphtheritic toxine.

In the light of his present renown, the personality of Dr. Roux by its extreme simplicity and modesty offers a subject worthy of closer observation. During the past year I have had an excellent opportunity of being impressed by it, my good fortune having brought me for a number of months into his daily presence, thus enabling me to see him in most interesting and exceptional moments. I was then one of a small number of doctors particularly interested in the work of the Pasteur Institute, who assembled before him to follow his unpretentious course on bacteriology. The nominal subject of the course was interrupted from time to time by Dr. Roux, and on such occasions the talks became a sort of familiar commentary on the general work of investigation actually going on at the institute. The chief interest at that time was soon seen to be concentrated on questions relating to diphtheria.

It was in the largest of Dr. Roux's own laboratories that the course was being given. The air of peaceful quiet of the distant corner of Paris where the Pasteur Institute stands is all the more intensified as you go up the silent stairways and enter the right wing on the second floor. There, at the end of the hallway, is a dingy door bearing the words, "Microbie Technique." This opens into the main portion of the laboratory. Large and numerous windows admit floods of sunlight and fresh air, and strewn about on all sides in apparent confusion are sterilizing apparatus, étuves for cultivating bacteria, rabbits, birds, guinea-pigs, rats, mice, all sorts of inoculated animals awaiting autopsy, with an almost infinite number of small test tubes containing a collection of all the microbes known to the present day.

Here in this room, nine months ago, every afternoon at half past one o'clock were assembled about twenty doctors, young and middle-aged men, waiting with quiet, concentrated faces the appearance of Dr. Roux.

Promptly at the appointed hour a small door opens at the side and in glides a tall, slim figure. No sound greets his entrance as with long strides he advances quickly to the center of the room, where, without preliminary remarks or formalities of any kind, he begins in a natural and modest voice to discuss the subject under consideration.

His presence as he stands there is peculiarly interesting. The careless simplicity of his black attire is emphasized by a queer-looking parson's vest which extends up, tightly buttoned, to the middle of his white collar, leaving no room for a necktie. The apparent indifference to exterior effect is moreover confirmed by the clumsy rubber galoches which he invariably wears, notwithstanding the popular French prejudice against their grotesqueness. The hair, like the thin, pointed beard, is black, and chopped all over as close as the barber's shears will permit, and covered at the crown with a tightly fitting little skullcap, also black.

The face is careworn and weary, colorless, almost sickly, in its aspect, with eyes pale and dim, though full of tenderness and sympathy. He produces the impression of a man still young, a man of forty.

A few quiet words and all thoughts of his physical peculiarities are quickly forgotten. With hushed attention the listeners are all absorbed, impressed by the magnetism of an earnest, powerful mind searching with conviction for the truth.

From time to time, as we were assembled in the laboratory as usual, Dr. Roux put aside the previously commended subject to inform us of the investigations that he was making in reference to diphtheria. We listened to his simple explanations in these eventful moments, little realizing that new and great principles were declaring themselves, and that these, together with what was being done in Germany, would complete a discovery which with its inestimable benefits would so soon agitate the world.

The center of the new experiments, Dr. Roux explained to us, was a horse. Into this animal had been injected at long intervals during a number of months considerable quantities of the toxine produced in the laboratories by the cultures of the Klebs-Loeffler bacillus.

A number of smaller animals, as the doctor proceeded, were brought before us. These animals had been given the disease by inoculation, then subsequently had received injections from serum prepared from the blood of this horse. Instead of dying of diphtheria, as had hitherto been customary, nearly all had recovered as a result of the injections and were actually enjoying the best of health.

The experiments were to be repeated, and Dr. Roux stated in conclusion that, if the results were verified and confirmed, as he hoped, the treatment would be immediately applied to diphtheritic children.

As he ended this announcement and retired quickly through the door at the side, the little group remained in its attitude of attentive silence. He disappeared as he had come, without a sound of applause, while the seriousness of his words impressed and prolonged itself in the minds of his hearers.

How fragile and exhausted he looked as he hastened out of the room to push on with restless enthusiasm the work in his private laboratory—morning, noon, and night, week days and Sundays alike, without a thought of recrea-
tion, nothing but ceaseless, unremitting work! And often with anxious eyes we followed his disappearance, fearful that something would happen to him, that overstrain might impose a serious interruption to that precious mind with its many problems still unsolved. And each following day at half past one a thankful sense of relief came over us as the little door again opened punctually to admit the same dark, slim figure with its pale, delicate face that seemed almost pathetic.

The work is now accomplished, the experiments have been repeated and verified, the treatment has been applied to diphtheritic children. In September Dr. Roux read his report on three hundred and twenty cases treated in Paris at the congress at Budapest, and at once became a national hero. He has been elevated to the grade of commander in the Legion of Honor; large sums of money have been placed in his hands by the spontaneous impulse of the people and the official will of the government; published articles in France have ranked him among the eight or ten most celebrated men in the world.

Let us return once more to the Pasteur Institute to witness for ourselves the changes that have taken place there as a result of these unusual circumstances.

It lacks but a few minutes of half past one as we enter the hallway on the second floor and again approach the dingy door at the entrance of the familiar laboratory. The aspect of the room is indeed no longer the same. Instead of the serious little groups that our eyes had become accustomed to, we see a strange collection of humanity crowding the place to its utmost capacity.

A more diversified spectacle of costumes and faces could not well be seen in modern times. Russians, Roumanians, Canadians, Greeks, Japanese, Egyptians, masculine-looking women from Scandinavia or St. Petersburg, Turks in their red fezes, men of the north and the south, of the east and the west, whom the fame of the great discovery has reached in their distant homes and assembled here in this quiet laboratory to hear the words of Roux. Two priests, crowding in at the last minute, are obliged to stand with their backs to the sterilizing apparatus.

At half past one all eyes turn again toward the little door, which opens punctually on the minute. No apparent change has taken place in the dark, slim figure that glides in with accustomed quickness. The careless attire, the tightly buttoned vest, the clumsy gait, and the black skullcap on the closely cropped head—all the same as before, with the single exception of a large red button resting on the lapel of his coat which marks a commander in the Legion of Honor.

The pale, earnest face is slightly older and is more careworn with its heavier responsibilities. Those familiar with Dr. Roux notice an almost imperceptible air of embarrassment that betrays itself in the presence of the too numerous and strangely anomalous audience. It is only for a minute, however; when once he has begun in his unassuming voice, all irrelevant circumstances are forgotten as before. He mentions incidentally the sixty-two horses now in the control of the Pasteur Institute that have taken the place of the single one of last winter; then the new and extensive improvements that were necessary for the increased production of serum. He also describes the duties of a number of thoroughly trained and skillful bacteriologists who are associated with him in this department, and to whom he intrusts many of the delicate details so important to secure a serum of the proper quality. He then speaks of the latest results obtained by the serum therapy in the diphtheritic pavilions of the two largest children's hospitals in Paris—the Hôpital des enfants malades and the Hôpital Trousseau.

The mortality has been steadily diminishing. This improvement seems to go hand in hand with the perfection in the methods of preparing and administering the serum, and with the increased facilities for the isolation of the cases complicated by broncho-pneumonia, scarlet fever, measles, etc.

The last two hundred and thirty-one cases treated at the Hôpital Trousseau, and reported December 13th by M. Moizard, showed only thirty-four deaths. He included in this list every child that had been admitted to the diphtheria pavilion, no matter how bad its condition had been on admission, and only those in whom the Klebs Loefler bacilli had been found. Of the last two hundred and sixty-seven patients treated at the Hôpital des enfants malades, in the service of M. Bréton and Caillon, only twenty-seven died.

Now, after the close of his lecture, let us follow him into his private laboratory and there see one of the frequent interviews that await him. You can thus learn his real sentiments in the midst of his glory. Before an authorized visitor who addresses him with formal and complimentary language, a sort of trouble seems to come over him, a fear of not appearing sufficiently simple, of something in his manner that might be mistaken for pride. Then, as the conversation continues, he becomes visibly uncomfortable and impatient. He usually ends up by throwing off all appearances of conventionality to take refuge in the free and easy expressions of a medical student. The newspapers exasperate him with their noisy exaggerations, and his greatest desire would be to run away from the commotion to some spot where he could continue his work in peace. To be able to do this and to escape all official and unofficial congratulations, he would, I feel quite sure, without hesitation sacrifice his great scientific renown and his position in the Legion of Honor, and become once more a simple investigator unknown to all but his microbes. His only ambition apparently is to advance the field of scientific research, not for his own reputation, but for the glory of the Pasteur Institute and in hopes of discoveries that may relieve human suffering.

And, still, a month ago when I interrupted him to ask as a favor a little of his precious serum to take back to America, an expression of kindly sympathy lighted up his pale, careworn face, and with a friendly word for America he, in his own simple way, granted my request.

The North Carolina Medical Journal.—In the first number for 1895, dated January 5th, it is announced that henceforth the Journal will be published twice a month. We are glad to see this sign of its prosperity.
GASTRIC CONDITIONS IN RENAL DISEASE.*

BY ALLEN A. JONES, M.D.,
CLINICAL INSTRUCTOR IN MEDICINE AND INSTRUCTOR IN PRACTICE,
MEDICAL DEPARTMENT, UNIVERSITY OF BUFFALO.

The kidneys may be the seat of considerable morbid change and yet possess the power of excretion that is essential for the welfare of the whole organism. On the other hand, the kidneys may be intact as to their structure and yet be so functionally sluggish that more or less uremia results. As in a diseased heart, the question is not so much as to the exact deformity of the valves, but is more pertinently directed to the dynamic condition of the heart muscle, so in renal disease the inquiry as to the extent and nature of the organic lesion is subordinate to the determination of the excreting power of the organs.

In reference to the causative relation between renal disease and gastric disturbances, the point of greatest importance is not the nature of the inflammation or the change in the kidneys, but is one mainly bearing upon the elimination of urea and other poisons by these organs.

Chronic catarrhal gastritis is one disorder of the stomach that occasionally results from some chronic form of renal disease, as, for example, interstitial or chronic diffuse nephritis. The mere fact, however, of the existence of disease of the kidneys is not of itself sufficient to account for the gastritis, as many cases of manifest renal disease do not have catarrhal gastritis. The blood-state resulting from imperfect elimination by way of the kidneys disturbs the innervation and the circulation of the stomach, and in certain patients whose stomachs possess a low resisting power, catarrhal gastritis may supervene and take its place in the morbid cycle thus induced.

The nutrition of the patient may suffer materially as the increasing anemia and the steady loss of weight and strength may show, and this general failure is due in part to the disease of the kidneys and in part to the impaired state of the stomach.

This fact emphasizes the importance of examining the stomach in cases of manifest disease of the kidneys just as, on the other hand, the urine should be carefully studied in cases of gastric disorder.

If gastric symptoms are present in catarrhal gastritis, they are usually indefinite and changeable. Loss of appetite, nausea, vomiting, eructation, pyrosis, weight and distress in the epigastrum, pain of greater or less severity—a few or all of these symptoms may be complained of at different times. They are, as will be seen, not distinctive of catarrhal gastritis or of renal disease, and only by examining the stomach contents and the urine are we able to arrive at a knowledge of the true state of affairs.

The chemistry of digestion is usually somewhat changed in this form of gastric catarrh. Hydrochloric acid is secreted in only small quantities and is likely to progressively diminish as time wears on and the gastric glands atrophy. Owing to the debilitated condition of muscular tissue everywhere in chronic renal disease, the musculature of the stomach loses its tonicity, and motion becomes sluggish and inefficient. There is, however, no absolute rule in this matter of gastric motility, as in a proportion of cases the viscus empties itself hurriedly in spite of its flabby condition, while in other cases the motor power of the stomach appears changeable from day to day. If hydrochloric acid is subnormal and if the stomach allows food stagnation to occur in any degree, lactic acid is very apt to be formed by fermentation of the stomach contents. Such fermentation is especially the result of improper diet coupled with the predisposing conditions above mentioned.

In old people who have fibroid hearts, thickened arteries, and contracted kidneys the stomach is often the seat of the same element of parenchymatous atrophy with formation of new connective tissue that eventuates in thinning of its mucous membrane and the disappearance of some of the gastric glandules. How far this condition of the gastric mucosa in old age depends upon the fibroid state of the kidneys it is difficult to say. It is reasonable to suppose that in many cases the renal disease and the gastric changes are concomitant results of a common cause, or that the morbid state of the kidneys is partly the result of the action of noxious and irritating products arising from disordered gastric digestion.

Again, there are many old people whose kidneys are the seat of chronic diffuse nephritis, the parenchyma of the organ being chiefly involved; whose arteries show but little change; whose hearts give no reason to conclude that fibrosis has occurred in them to any extent; and whose stomachs are free from pronounced inflammatory change, and in these cases, at the beginning, digestion is carried on correctly, becoming impaired only when the gradual failure in the general health and strength of the patient reaches a point whereat muscle and nerve and glandular tissue fail because of vitiated and imperfect nutrition.

The previous habits of the patient exercise a large influence upon the resistance his stomach will show to the deprivd blood-state accompanying renal disease. Excess in the use of alcohol, morphine, cocaine, tobacco, tea, and coffee inevitably aggravates existing gastric disorder, and certainly intensifies the morbid condition of the kidneys.

The degree of so-called uremia and the general condition of the patient, his nervous symptoms, his bowels, circulation, and so on, are points of much importance in the consideration of a case of gastric disease associated with, and partially secondary to, some form of renal disease, and the functions of the stomach may be restored in some degree if the uremia is not too profound and unyielding.

Chronic catarrhal gastritis is by no means the sole disorder of the stomach occurring in connection with disease of the kidneys. I have found hyperchlorhydria associated with severe pain in cases of more acute renal inflammation or irritation, but no catarrhal gastritis was present. In one case, particularly of this nature, the patient gave a history of having contracted syphilis seventeen years before I saw him. Examination of his urine disclosed the presence of albumin and a few granular casts. The stomach was found entirely free from food four hours after a plain mixed meal, but there was withdrawn about a pint of clear viscid fluid which had a total acidity of forty per cent. due

* Read before the Buffalo Academy of Medicine, November 15, 1894.
entirely to free hydrochloric acid. The secretion of hydrochloric acid is sometimes diminished, and fermentation, giving rise to the formation of organic acids—lactic, acetic, and butyric—is set up without there being any appreciable gastric catarrh. In cases of kidney disease I have found achylia gastrica (Einhorn), and this condition may have depended somewhat upon the morbid state of the kidneys. In all probability some renal diseases are in a measure due to defective gastric chemistry. It is a most difficult matter to determine which disease occurs primarily in many cases of gastric disturbance coupled with albuminuria, casts, and diminished excretion of urea. The blood-state called “uremia” results from the absorption of certain poisons formed probably somehow and somewhere in the gastro-intestinal tract, and these poisons cause nephritis as the kidneys endeavor to effect their elimination. The kidneys are excreting organs, and in uremia there is something more than their failure to rid the blood of poisons ordinarily formed within the body in a healthy condition of digestion, absorption, circulation, and assimilation. There must be some unusual toxin or toxins elaborated within the body independent of and before the onset of nephritis, which toxin sets up inflammation in the kidney, and then a morbid cycle is established in which continued auto-intoxication (uremia) occurs, while the eliminating power of the kidneys is steadily lessened by inflammatory changes. (See an excellent paper bearing upon this point by Hughes and Carter in the American Journal of the Medical Sciences, August, 1894.)

Severe gastalgia may occur in patients whose urinary examination reveals the presence of albumin and casts. In some of these cases gastric chemistry is about normal, while in others the secretion of gastric juice may oscillate above and below the normal point. In a few cases the gastalgia depends partly upon the irritating action of a large amount of highly acid gastric juice secreted in an empty stomach (supersecretion and hyperchlorhydria). In those cases having non-irritating gastric contents the gastalgia depends upon the action of the poison the kidneys fail to eliminate, or upon impoverishment of the blood, or upon reflex disturbance from disease of other organs, or upon hysteria, disease of the central nervous system, syphilis, or a variety of causes. In many cases of essential gastalgia, as well as in other forms of gastric complaint, in hysterical females elimination of urea is notably decreased. It is not uncommon to find only eight or ten grains of urea excreted in twenty-four hours. These cases are very promptly improved by forced perspiration (thermal baths) and active catharsis, not only in the matter of their gastalgias, but also in their renal elimination, which usually rises rapidly toward a healthy sufficiency. Gastalgia may occur associated with, though independent of, inflammation of the kidneys, as, for instance, in the case of a man under my observation some time ago who had beginning locomotor ataxia with gastric crises, and in whose urine albumin and casts were found. In middle-aged women who are the victims of that very obscure malady known as arthritis deformans, attacks of agonizing gastalgia are common, while a very slow form of diffuse nephritis is evidenced by intermittent mild albuminuria with a few slightly granular casts and somewhat diminished elimination of urea. The urinary conditions in some cases are not constant, but there is reasonable ground for concluding that nephritis exists.

In these cases the gastric disorder usually precedes the joint and renal troubles, although there may be no complaint of the stomach made by the patient. The gastric chemistry is faulty, or the stomach empties itself into the duodenum too hurriedly after each meal, or gastric motion is insufficient, allowing food stagnation and fermentation. Imperfect digestion means depraved, polluted blood, which in turn causes slow organic changes in remote organs of the body.

Renal calculus is prone to excite reflex disorders of the stomach, especially during attacks of nephritic colic when vomiting is apt to supervene and assume some severity.

Other symptoms than vomiting not infrequently seem to be due to a dependent relation to renal calculus, such as eructation, regurgitation, weight, distress, burning, and pain. I have found achylia gastrica in cases of renal and biliary calculi in men past middle age, and it is not improbable that in such cases the digestive disorder stands in some causative relation to the urinary and biliary conditions that favor the formation of calculi.

Floating kidney is a well-known cause of many gastric disturbances. It is usually associated with dilatation of the stomach, and the right kidney is most commonly found movable. Eructation, pyrosis, nausea, and vomiting are the most common gastric symptoms accompanying movable kidney; and as these symptoms have disappeared in many cases after the operation of nephrocrania, it is reasonable to conclude that they depended upon the displaced kidney. The gastric disorder in renal dislocation is in part the result of mechanical traction and in part it is a reflex disturbance.

In a great many cases, however, the gastrectasis exists in a marked degree, and food stasis occurs, with occasional attacks of copious vomiting, persistent constipation, and many of the ills resulting from dilatation of the stomach. In these latter cases many, if not all, of the gastric symptoms may be overcome and the general health of the patient may be remarkably improved by appropriate treatment of the stomach without bringing the kidney to anchor by operation.

436 Franklin Street.

The Pennsylvania State Medical Society.—We have been asked to say that members who wish to read papers at the meeting to be held in Chambersburg, on May 21st, 22d, 23d, and 24th, are requested to send their names and the titles of the papers they wish to read to the chairman of the committee on scientific business, Dr. Charles W. Dulles, No. 4101 Walnut Street, West Philadelphia. The committee desires papers to be absolutely short enough to be read in ten minutes. At the last meeting a large number of interesting papers were not read because those preceding them were too long, and it is hoped that those who prepare papers for the coming meeting will condense them as much as possible. The laws of the society permit each writer to occupy twenty minutes, but it will be of advantage if the members do not avail themselves of all their privilege.
THE QUESTION OF THE
Efficacy of Subconjunctival Injections of Mercuric Bichloride
In Ophthalmic Therapeutics.*

By CHARLES STEDMAN BULL, A. M., M. D.,
Professor of Ophthalmology in the University of the City of New York;
Surgeon to the New York Eye and Ear Infirmary.

The attention of ophthalmologists to the supposed beneficial effects of subconjunctival injections of mercuric bichloride in ophthalmic therapeutics was first generally attracted by the papers and publications of Darier, an assistant of Abadie's clinic in Paris. Intracocular injections had for some time previously been employed in the treatment of certain diseases of the eyeball, notably by Abadie in cases of sympathetic ophthalmia (1889), and in certain syphilitic lesions of the eye (1890). Secondi had also claimed good results in the treatment of sympathetic ophthalmia by subconjunctival injections of sublimate. Darier's interest in the subject had been stimulated by his observations on the effects of the intracocular injection of tincture of iodine employed in cases of detachment of the retina, which he carried on in conjunction with Dubarry; his attention being particularly attracted by the rapidity with which dilute solutions injected into the eye were absorbed without producing any grave symptoms. Subsequently (1891) he employed subconjunctival injections in cases of traumatism, and claimed that he thus gained a really efficacious antiseptics. In all his subsequent experiments he has worked upon the theory that the aim of all therapeutic measures in the management of localized infectious diseases should be to inject some antiseptic agent into the infecting focus or its immediate vicinity, so as to irrigate and render aseptic the entire lymphatic territory in which the morbid process is located. He claims that physiology has taught that colored solutions injected under the conjunctiva rapidly penetrate the cornea, aqueous humor, lens, vitreous, and deeper coats of the eye. His experiments included the entire field of inflammatory lesions and traumatisms of the eyeball. He uses a Pravaz syringe, the needle having an iridized platinum point, and he produces local anesthesia of the parts by cocaine. When complete conjunctival insensibility has been produced, he seizes the ocular conjunctiva by forceps at a point from six to eight millimetres from the corneal margin and injects the necessary quantity of liquid obliquely beneath it. All the steps of the operation are performed with extreme antiseptic precautions. He claims that the edema and pain resulting from the injection vary according to the amount of liquid injected and the peculiarities of the patient. He uses a solution of mercuric bichloride of one to one thousand, and injects a twentieth of a milligramme at a time, though the dose he claims may be varied according to the severity of the disease. The number of injections necessary vary from three or four to fifty or sixty, according to the degree of chronicity of the disease, but if after ten injections no result is obtained, he considers it useless to continue the treatment. He claims to have had no serious complications, other than the severe pain, the conjunctival edema, and occasionally some ecchymosis or hemorrhage. He draws the following conclusions: In all cases of infectious disease, acute or chronic, primary or secondary, the result of mechanical irritation, like erosion of the cornea or severe traumatism, or of infection from within, whether reflex, metastatic, syphilitic, or hemorrhagic, subconjunctival injections of sublimate offer the most rapid and energetic method of limiting the morbid process. This local therapeutic agent does not, at all limit the general treatment, but rather acts as an efficient aid in the treatment of the case.

Chibret has employed this method in the treatment of syphilitic diseases of the eye, and regards it as the best method, but prefers a solution of the cyanide of mercury to the sublimatic solution. He speaks of severe pain and diarrhea occasioned by the injections, and recognizes the latter as a sign of general poisoning by the drug, which must be actively combated when it occurs. (Annales d'oculistique, July, 1893.)

Gegner (Ctribl. f. prakt. Aug., January, 1894) considers that if this method is faithfully and impartially tried, it will be found in many cases to be the best and surest method of treatment, and that its employment is justified in all cases in which mercurials are indicated. He recognizes that injections of sublimatic solutions cause a deposit of albuminates in the lymphatics, but thinks that a certain portion of the injected fluid is still distributed through the tissues and acts directly on the diseased germs, either by killing them or enfeebling their activity, and thus materially shortens the duration of the disease.

Terson (Ann. d'oc., May, 1894) considers that the utility of subconjunctival injections of sublimate has been fully demonstrated. He reports one case of serious episcleritis which was rapidly healed by this method. He has, however, obtained very contradictory results—some remarkable successes, some cases of complete failure, and not a few cases in which the condition was made decidedly worse.

Sgrossso (Trans. of the Thirteenth Ital. Ophthal. Congress, Palermo, 1892, and Annali di ottalnologia, 1893, fasc. 6) gives the honor of priority for this treatment to Secondi. He employed subconjunctival solutions of sublimate in eighty-five cases of all varieties of disease of the eye, and found that the severity of the symptoms was modified and the duration of the disease materially shortened in corneal abscesses and ulcers, and parenchymatous keratitis. Abscesses with hypopyon seldom required more than one or two injections. In iritis, however, the method gave doubtful results, and gummata were made worse by its use, and no benefit resulted from its employment in cases of neuro-retinitis and sympathetic ophthalmia.

Pfeunov (Wjesnik Oftalnologii, May–June, 1893) considers that subconjunctival injections of sublimate are the simplest and best local means of treatment in diseases of the deeper coats of the eye, especially in sympathetic ophthalmia, and believes that the favorable effects of the treatment are due to the rapid absorption of the solution.

* Read before the Section in Ophthalmology and Otolgy of the New York Academy of Medicine, December 17, 1891.
and to the acute irritative symptoms which follow the injection, which cause a rapid exchange of the nutritive fluids.

Gallinaerts (Bull. de l'Acad. roy. de Belgique, 1893) has found sublimate injections very valuable, especially in cornal troubles, sympathetic ophthalmia, and purulent processes after traumatism. He claims that under cocaine they cause no pain. He has used it eight hundred times, and has never seen a bad result.

Grand-Clément (Lyon méd., April, 1893) found sublimate injections of little value in corneal infiltration, and of no value in diseases of the retina and optic nerve, but considers them very useful in diseases of the iris and chorioid.

Gagarine (Peterburger Inaugural Thèse, 1893) found subconjunctival injections of sublimate of great value in gummatus iritis, plastic and purulent iritis, and chorioiditis, but thinks them of little or no use in parenchymatous keratitis and scleritis.

Venneman, Coppez, Lagrange, and Motais (Ann. d'oc., August, 1893) all agree in attributing excellent results to the treatment by subconjunctival injections of sublimate in cases of acute and chronic irido-chorioiditis and sympathetic ophthalmia. Lagrange goes so far as to maintain that the sublimate solution enters the anterior chamber by means of the interstitial lymphatic channels, and thus acts locally on the diseased tissues.

Vossius (Ann. d'oc., August, 1893) also claims good results from their use in parenchymatous keratitis and in chorioiditis, and Rogman agrees with him.

Pitneyger (Ann. d'oc., August, 1893), on the contrary, has abandoned the use of mercurials by subconjunctival injections, but alleges equally good results from solutions of trichloride of iodine, in the strength of 1 to 2,000.

Among those authors who do not believe in the efficacy of subconjunctival injections of mercurials, or are opposed to their use, may be mentioned the following:

Wecker and Masselon have not found that they produced any favorable result when used alone without the aid of other means.

Laqueur found that sublimate injections were borne well enough, but produced no effect on the course of the disease, and he has abandoned them.

Both Dianoux and Beneffe agree in the main with these conclusions.

Haab has employed them in cases of interstitial keratitis without any beneficial result.

Michel is of the opinion that the method of subconjunctival injections does not accord with the principle of ocular asepsis.

Cohn objects to them on account of the severe irritation and reaction induced by their employment.

Samsoln, Landolt, and Panas all object to their use on theoretical grounds. The latter asks if it is supposed that the injections produce their effect by chemical action, which he considers impossible in the homoeopathic dose in which they are administered, and furthermore, if so, it would be necessary to prove absolutely that the drug penetrates the eyeball, and this has never been done.

The most recent and important criticism on the therapeutic value of these subconjunctival injections has been made by Muternich (Ann. d'oc., September, 1894). He does not believe that the sublimate solution reaches the diseased focus more readily when injected beneath the conjunctiva than when instilled into the conjunctival sac, while it does cause certain disagreeable complications which may lead to disastrous results. He quotes the work of Bellarminoff to prove that solutions instilled into the conjunctival sac pass immediately through the cornea in quantities much larger than if these same solutions were injected beneath the conjunctiva. Up to the present time we have no sufficient facts to prove the diffusion of sublimate solutions through the coats of the eye. The diffusion of different soluble substances varies within wide limits, and some of these solutions never penetrate into the anterior chamber at all. The experiments of Tichomoroff with sublimate gave a negative result. If we admit the bactericidal power of sublimate solutions, we must assume that they actually reach the diseased focus—that is, that they must penetrate all the membranes and fluids of the eye uniformly. This would eventually end in such extreme dilution as would be deprived of all antiseptic action. The advocates of the subconjunctival plan of treatment usually inject one twentieth of a milligramme at a time. A part of this passes into the general circulation and is lost as far as the eye is concerned; another portion is eliminated into the conjunctival sac through the conjunctiva itself. This leaves scarcely one third to penetrate into the interior of the eye, or about one sixtieth of a milligramme, which is too minute to possess any antiseptic power. Hence the claims of the partisans of the method by subconjunctival injection, that under its use hypopyon is absorbed very rapidly from the anterior chamber, can not be accepted, for its bactericidal power has been lost by dilution. More can be expected from instilling the solution into the conjunctival sac, especially in cases of corneal ulceration, for the penetration of soluble substances through the cornea is materially favored by loss of its epithelium. In regard to the use of this method in the treatment of sympathetic ophthalmia, its partisans, Darier, Gepner, Pjeneoff, and others, accept Deutschmann's theory as to the parasitic nature of this disease. But it must be remembered that this theory does not explain all the clinical signs nor the mode of development of sympathetic ophthalmia, and that it is opposed by scientific facts generally accepted, and which can not be refuted. Deutschmann's theory can not be regarded as substantiated until we can prove that the micro-organisms which cause sympathetic ophthalmia can transport themselves from place to place, and even travel against the current of the fluid in which they float. Up to the present time no actual observation has been made of the metastasis of an ocular neoplasm from one eye to another. Hence sympathetic ophthalmia can not be regarded as due to micro-organisms, but rather as dependent upon certain other factors as yet unknown. Muternich sums up his criticism in an epigrammatic way by asserting that, in treating sympathetic ophthalmia by subconjunctival injections, we are guilty of a double mistake in trying to destroy organisms
which do not exist by a remedy which has no bactericidal power. He also thinks that Gepner has been guilty of a great error in attributing the success of his treatment of myopic choroiditis to subconjunctival injections by forgetting the conditions in which these patients were, and in neglecting the most powerful of all the factors which favorably influence the progress of the disease—viz., the absolute repose of the eye.

My own experience has not been very extensive. During the past year I have employed subconjunctival injections of sublimate solutions in the treatment of various diseases of the eye in forty-eight cases, which were classified as follows: Interstitial or parenchymatous keratitis, six cases; abscess of the cornea with hypopyon, eight cases; sclerosis and episcleritis, two cases; syphilitic iritis, ten cases; irido-chorioiditis, syphilitic and non-syphilitic, fifteen cases; traumatic orbital cellulitis, three cases; sympathetic ophthalmia, two cases; syphilitic neuro-retinitis, two cases.

The solution employed was of the strength of 1 to 1,000 and the amount injected at each operation was one twentieth of a milligramme, as recommended by Durian.

Of the six cases of parenchymatous keratitis, four were instances of unilateral inflammation of the cornea and two were bilateral. The youngest patient was nine years of age and the oldest seventeen. Of the eight eyes involved, three were of the vascularized variety. All were chronic and resisted more or less markedly the usual methods of treatment employed in such cases. The number of injections varied from three to ten at intervals of a week. In three of the eight eyes there was severe reaction following the first injection, lasting from four to eight days, but this did not occur after the subsequent injections and not at all in the other cases. In all, the pain caused by the injections was severe and lasted several hours in spite of the free use of cocaine before and afterward. In none of the cases was there any material effect produced by the remedy, either in lessening the severity of the symptoms or in shortening the duration of the disease. Allowing for the marked reaction in three of the eyes, none of the cases were made materially worse by the injections, and all eventually got well on reverting to the usual method of treatment by atropine, hot applications, leeches to the temples, and syrup of the iodide of iron and cod-liver oil internally.

In the eight cases of corneal abscess with hypopyon, all of which were of traumatic origin, there was severe reaction in three and slight reaction in five. None of the cases proved a total loss, but in none was there any apparent improvement in the symptoms or in the duration of the disease. The pain induced by the injections was severe in all, and in three cases the reaction was so severe as to excite fears of orbital cellulitis, which happily did not occur. Two of the eight cases ended in partial slough of the cornea. All the others recovered with good or partial vision under the use of hot bichloride applications (1 to 5,000), atropine, the galvano cautery, and bandaging.

The two cases of sclerosis and episcleritis were marked instances of the disease occurring in syphilitic patients, but without any circumscribed gummatous infiltration. The reaction in both was marked and the pain very severe, but the signs of irritation rapidly subsided, and the cases certainly progressed more rapidly to recovery than is seen under the usual form of treatment. One of the cases required but one injection and the second only three injections. I have had no opportunity of employing this method in gouty or rheumatic scleritis, and therefore am unable to express an opinion as to its efficacy in this very chronic and obstinate affection.

The ten cases of iritis were of the plastic variety and occurred in patients who were markedly syphilitic. None were of the gummatous variety. There was moderate reaction in six cases and violent reaction in four cases, so severe that I deemed it unwise to employ a second injection. I was unable to discern any improvement in the course of the disease by this method of treatment over the usual means employed in any case, and in the four cases in which severe reaction followed the injections the healing process was certainly retarded. Atropine was used in all cases. The pain induced by the injections was severe in all and lasted several hours.

Of the fifteen cases of irido-chorioiditis, eleven were in syphilitic patients, and in four cases syphils was presumably absent. The eleven syphilitic cases were all chronic and were accompanied by but slight exudation into the aqueous and vitreous. The four non-syphilitic cases were all acute and were accompanied by severe pain and considerable infiltration into the vitreous. In one of the syphilitic cases there was an apparent improvement in the symptoms and duration of the attack, the reaction induced by the injection being slight. In none of the other syphilitic cases could it be stated that anything was gained by this method, and the reaction was sometimes severe. In one case ten injections were given. In the four non-syphilitic cases a very decided improvement was noted in three, both in the clearing up of the vitreous and in the subsidence of the external signs of inflammation, and these cases recovered with very useful vision. In all the pain induced by the injections was severe and the resulting reaction was moderate.

The three cases of traumatic orbital cellulitis bore the injections extremely well. The injections were made very slowly and caused very severe pain, but there was almost no increase of any of the external signs of cellulitis. From one of the cases a foreign body had been removed from the orbit, and the injections were made in the tract of the wound. In spite of the absence of reaction the cases pursued the usual course, and it could not be claimed that the duration of the process was shortened in any of the cases. All recovered, two with very good vision and one with perception of light. There was less reaction from the injections in these cases than in any of the other cases in which the injections were employed. In all three it was necessary to make incisions into the orbital tissue before the process was stayed.

In the two cases of sympathetic ophthalmia the process was made decidedly worse by the injections. The pain was severe, the reaction very violent, the intensity of the symptoms increased, and the duration prolonged. Both
were cases of traumatism, comparatively recent, and in both cases injections were made beneath the conjunctiva of both eyes simultaneously. Both were advanced cases of sympathetic inflammation, and therefore perhaps unfavorable ones for the treatment. Only one injection was made in each eye, on account of the violent reaction which followed its use. If it were possible to express an opinion from two cases, I should say that I was disinclined to use this method in cases of sympathetic inflammation.

In the two cases of syphilitic neuro-retinitis, though the pain induced by the injections was severe, the reaction was very moderate, and in both cases I used seven injections at intervals of five or six days. Both patients recovered useful vision, and the edema and infiltration of the optic disc and retina nearly entirely disappeared, but I could not see that the treatment by injections brought about any shortening in the duration of the disease, and I should not employ it in such cases again.

The conclusions which I have ventured to draw from the above observations are as follows:

1. The pain induced by the injections is always severe, in spite of the persistent and careful use of cocaine.

2. The reaction is apt to be severe, and sometimes very severe.

3. The only classes of cases in which the sublimate injections seemed to exert any positive effect in allaying the severity of the symptoms and shortening the duration of the process were those of scleritis and acute irido-chorioiditis of the non-syphilitic type.

4. The method of treatment by subconjunctival injections of sublimate solutions is still on trial, and should not be promiscuously employed in all sorts of cases as part of or in place of the routine treatment. It must stand or fall on its merits, and these can only be ascertained by careful and long continued observation of a large number of cases. The severe pain and the occasional violent reaction produced by the injections must always be a bar to the universal employment of this method of treatment.

MULTIPLE GUNSHOT WOUND OF THE ABDOMEN, WITH RECOVERY.*

By M. L. BENNETT, M. D., WATKINS, N. Y.

On Sunday afternoon, August 26, 1894, between the hours of five and six, I was hurriedly summoned to Coal Point, a mile and a half distant from my house; the messenger said that an Italian laborer by the name of F. R., whose age was thirty-one years, had been shot by one of his companions only a few moments before he left him, and he scarcely thought the man would be living on my arrival. Having just returned from the country and being in my carriage at the time, I drove immediately to the spot, and there found the victim lying on the grass about two rods from where he was shot; he had attempted to walk, but had fallen from fainting and pain. I ordered him removed to a vacant house a few feet distant. After being laid down he soon vomited, and had vomited twice before while lying on the grass. He complained of great pain in the abdomen, which, on examination, revealed a bullet wound about an inch and a half to the right of and a little below the umbilicus; the abdomen was somewhat distended; pulse quick and feeble; respiration, 40; face very pale and anxious.

I immediately gave him a hypodermic of a fourth of a grain of sulphate of morphia, and sent for a carriage to remove him to his home in Watkins, having concluded to operate should my patient be in condition.

After making the necessary arrangements I called at the patient's house, where he had arrived a few moments before; I again made a hurried examination and found him suffering with much less pain, though the pulse was quite feeble, and he declared he could not live longer than a few moments; this, in my opinion, was partially due to fright accompanied by the great loss of blood.

Realizing that no time could be lost, we set about getting our patient in readiness. I was kindly assisted all through the operation by Dr. James K. King, of the Glen Springs Sanitarium.

After thoroughly cleansing the patient and ourselves and preparing plenty of sterilized water to be used with a fountain syringe, and after immersing my instruments in warm carbolized water, the abdomen was shaved and washed with bichloride of mercury solution and afterward with sulphuric ether. The patient was brought under the influence of chloroform administered by Dr. O. B. Crawford, of Watkins. Placing linen towels, previously wrung out in a warm bichloride solution, on both sides of the abdomen, I made an opening by an incision eight inches long, beginning a little above the umbilicus on the side of the wound and extending through the center of the linea alba to the pubes; after the peritoneum was opened between two and three pints of clotted blood poured out.

Beginning at the descending colon the intestines were carefully examined, and as fast as a wound was found I closed it with catgut sutures after Lambert's method.

There were sixteen bullet holes of the intestines found and closed, located in the caecum, ileum, and jejunum; after washing out the abdomen by using three or four quarts of sterilized water (warm), quite an amount of blood clot and fecal matter that had oozed through the wounds came away.

The abdominal wound, including the peritoneum, was closed with one silk stitching, leaving iodoform gauze at the lower end of the wound so that it reached down in the pelvic cavity. Iodoform powder was sprinkled over the edge of the cut surface and the wound was then covered with iodoform gauze and absorbent lint, and over all a roller bandage was applied.

He rallied quickly from the anesthesia and was put to bed about 11 p. m., having been under the operation for nearly four hours. After giving some general instructions we left our patient, and returned the next morning at nine o'clock, when we found he had passed a fair night, having been given a hypodermic of a fourth of a grain of sulphate of morphia; he had rested for six hours, having very little pain, a temperature of 99.5°, pulse, 100.

In the evening his temperature rose to 100.5° with the pulse about the same as in the morning.

I gave him liquid peptonoids in tablespoonful doses every three hours, and this was his diet for six days, with the exception of half a glass of milk.

Each day he improved, and at no time during the treatment did his pulse rise above 110 or his temperature above 102°; after the second day I began drawing out the gauze drain, and by the sixth day it was all removed, together with most of the abdominal sutures, leaving only a few at the lower end of the

* Read before the Elmira Academy of Medicine, November 7, 1894.
wound where the drainage had been, the entire wound above
the drain having healed.

On the morning of the 30th, four days after the operation,
he had three or four watery stools, though without pain; after
this the bowels would average one movement in from thirty-six
to forty hours. All movements of the bowels were made in a
bedpan while the patient was in a horizontal posture, which
posture was maintained for sixteen days.

After eight days I allowed him a change in diet, including
milk, eggs, custard, toast, codfish, etc. During his confinement
there was no distention or tenderness of the abdomen, except
around the cut surface.

On the seventeenth day I allowed him to sit up in a reclining
chair for an hour or so, and increased the length of time
each day thereafter.

On the twentieth day after the operation my patient began
complaining of pain in the left sacral region; on examination I
found distinctly feel beneath the tissues next to the bone what
I supposed to be the bullet.

On the following day I made an incision and removed a
32-caliber conical ball, very much battered; and on the tenth
day of October my patient resumed his former occupation as
section hand on the Northern Central Railroad.

A CASE OF
CHRONIC ADHESIVE PERICARDITIS,
WITH ENTIRE OBLITERATION OF THE SAC,
NOT DIAGNOSTICATED BEFORE DEATH.

By ELLWOOD OLIVER, M.D.,
ALBANY, N. Y.
HOUSE PHYSICIAN, ST. PETER'S HOSPITAL.

My object in reporting the following case to your jour-
nal is twofold. First, because the conditions found post
mortem show the case to be a somewhat rare one. Sec-
ondly, that other practitioners, especially the younger ones,
when they meet with a case which gives a history and signs
paralleled to this one, may always bear in mind the possi-
bility of such a form of pericarditis and thereby not fail a
victim to the error which I made in overlooking it. In
perusing the case you will note that there was neither
ystolic, precordial retraction, nor Friedreich's "diastolic
collapse" of the jugular veins to be seen. The case is as fol-

Mr. H. B., aged fifty years; born in Ireland; resident of
Albany; stonecutter by occupation; single.

Family History.—Negative.

Early History.—Nothing could be learned of his history,
other than that he had been a hard drinker up to about three
years ago, when he began to be troubled with a cough, worse
at night, and a thick, yellowish expectoration. Some time after
this noticed getting out of breath easily. At times, after much
exertion, breathing became asthmatic. About July 1, 1864, no-
ticed that his water gave very small in quantity; that his
breath became short upon the least exertion; that he frequently
had attacks of asthmatic breathing. His appetite became very
poor, and, his surroundings being very meager, he grew gradu-
ally weaker, and on August 18th entered St. Peter's Hospital,
practically exhausted.

Subjective Symptoms.—Great weakness; shortness of breath;
cough, worse at night; slight yellowish expectoration; dizzi-
ness upon rising from a chair or getting out of bed; loss of sleep
and appetite; poor memory; constipation; making small amount

of water; speech sluggish; patient stupid; disposition uninvit-
ing; temperament phlegmatic.

Physical Examination.—Some emaciation; skin pale and
bloodless, with slight dusky tinge; eyes dull; tongue moist
and slightly contorted; neck short and bent forward; sterno-mas-
toid muscles stand out; chest barrel-shaped; epigastric angle
quite obtuse; respirations accelerated; marked abdominal
breathing; chest moves up and down with respiration; retrac-
tion of intercostal spaces in lower part of chest on both sides
on inspiration; clavicles not prominent; apex beat not seen.

Pulse, 96, small, thready, weak, regular; beady feel to radial
arteries; temperature, 96° F.; vocal fremitus increased over
right apex, otherwise negative; apex beat of heart not dis-
tinctly felt.

Dullness over right apex, otherwise hyper-resonant over
both lungs; cardiac dullness slightly increased; liver and
spleen dullness normal.

Harsh respiration with prolonged expiration over both lungs;
bronchial breathing over right apex; sonorous, sibilant, and at
times medium moist rales heard on front and back; fine moist
rales heard occasionally over right apex; heart sounds very fee-
bly; pulmonic second sound accentuated; apex beat very faint,
heard best in fifth left interspace, three inches and a half from
mid-ternal; no murmurs.

Urinary Examination.—Specific gravity, 1:010; urates;
trace of albumin; no casts.

Sputum Examination.—Negative.

The case was diagnosed pulmonary emphysema, fibroid
phthisis of right apex, weak, fatty heart, and arterial atheroma.

Under rest, good diet, and internal medication he improved
for a time, then at intervals of a week or two attacks of dyspepsia
would come on after the least exertion, and at times without
exertion. During the early part of October he had an attack of
dyspepsia which lasted about two days. On November 14th was
taken with an attack of asthmatic breathing which did not give
way to treatment. Pulse, 96; temperature, 96°4°; respirations, 26;
sonorous and whistling rales heard on inspiration and expec-
tion. He attempted to get out of bed on the following day and
fell from dizziness. On the 18th breathing was less asthmatic,
but rapid and superficial. Pulse, 76; temperature, 98° F.; pa-
tient semi-delirious. Died on November 21st.

Post-mortem revealed the following: Both pleura greatly
thickened, firmly adherent to each other, the chest walls, the
diaphragm, and the lungs; both lungs emphysematous; hypo-
static congestion of bases; fibroid degeneration of right apex,
same containing four or five small cavities the size of a hazelnut
or smaller; the pericardium firmly attached to the surrounding
structures, the two layers greatly thicken and firmly adherent;
the heart firmly attached to the pericardium, thus entirely ob-
literating the sac; as the heart was freed from the sac, its surface
presented a papillary or hairy appearance; the ventricular walls
thickened and fatty; right ventricle full of blood, left contained
small clot; small thickened nodule (fibrous) on one of the aortic
semilunar valves, otherwise valves normal; three small patches
of atheroma on internal surface of ascending aorta; coronary
arteries atheromatous; liver, spleen, and kidneys congested.

A Thief caught by a Doctor.—Dr. W. Whitehead Gil-
fillan, of Lexington Avenue, returned to his house last Satur-
day afternoon in time to catch a thief who had stolen two
overcoats while pretending to await the doctor's arrival. The
man, Edward Dunn, said to be in the employ of a Bond Street
photograph firm, has robbed many physicians, and Dr. Gil-
fillan, who has had him indicted, is entitled to the thanks of
the New York profession.

NEW YORK, SATURDAY, JANUARY 19, 1895.  

OBSTINATE HICCough.  

Mr. W. Langford Symes, L. R. C. S. I., L. R. C. P. I., contributes to the January number of the Dublin Journal of Medical Science an exceedingly interesting article entitled A Study of Obstructive Hiccough. Mr. Symes gives the history of a case, and considers the general subject of persistent hiccough as regards its etiology, its pathology, its prognosis, and its treatment. In regard to the pathology of hiccough, he states the current belief to be that it is a reflex spasm of the diaphragm with simultaneous closure of the glottis, the pulmonary being the afferent nerve concerned and the phrenic and recurrent laryngeal the efferent nerves. He, however, questions this agency of the phrenic nerve, but thinks the sympathetic connections of the semilunar ganglion far more likely to be involved. For this he gives the following reasons: 1. The diaphragm appears to contract before the laryngeal muscles, and this points to a closer and more direct communication with the gastric portion of the vagus than with even the recurrent laryngeal. 2. The course of the phrenic nerve is healthy and its respiratory function perfect. 3. The patient has no control over the spasms, whereas the phrenic nerve is always subservient to the will. 4. Remedies applied to the origin or over the course of the phrenic nerve or to the cervical spine—such as blisters, ice-bags, compression, etc.—have no effect, while those directed to the diaphragm, the stomach, and the solar plexus are generally effective. 5. The connection between the pulmonary and phrenic nerves by means of the third, fourth, and fifth cervical nerves is remote, and were this the route taken the impression must travel more than double as fast on the phrenic nerve as it does on the recurrent nerve, since it reaches the diaphragm before the larynx—conditions, the author remarks, which are unphysiological. 6. Romberg's and Bright's experiments show that direct irritation of the phrenic nerve will not produce hiccough. 7. There is a perfect reflex loop between the stomach and the diaphragm which answers the purpose more directly, separated from the function of respiration and beyond the patient's control. 8. Hiccough is influenced by swallowing and by vomiting to a greater degree than by any respiratory effort.

Some clinical evidence is on record in favor of the agency of the phrenic nerve in the production of hiccough. One piece of this evidence, among others, is the statement by M. Leboir that he has stopped hiccough in a child twelve years old by pressing with the finger for three minutes on the phrenic nerve between the two attachments of the sterno-clidio-mastoide muscle, also that he had resorted to this method in a great number

MINOR PARAGRAPHS.  

THE PHYSICIANS' MUTUAL AID ASSOCIATION.  

At the twenty-sixth annual meeting of the New York Physicians' Mutual Aid Association, to be held in the Academy of Medicine's building next Thursday afternoon, important amendments to the by-laws will be proposed, and it is highly desirable that the sense of the meeting should represent that of the members as closely as possible. On that account, among others, it is to be hoped that the attendance will be large. The annual report of the board of trustees will be presented, and officers for the ensuing year are to be elected. The affairs of this association now concern so large a proportion of the profession in the city, as well as a considerable percentage of the physicians of the State, that it is more than ever necessary that they should continue to be administered with the prudence and carefulness that have placed the association on its present satisfactory footing.

DR. KÁLLAY'S AERZTLICHER ALMANACI.  

The fourteenth annual issue of this very useful handbook, for the year 1895, has lately reached us. It has the usual range of contents, including a diary for the year, and is embellished with a portrait of Professor Behring.

ITEMS, ETC.  

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending January 15, 1895:

Dr. William Osler, of Baltimore, authorizes us to state that he has not accepted the principalship of McGill University, and that he has no intention whatever of leaving the Johns Hopkins University.

The Society of Medical Jurisprudence.—The special order for the last meeting, on Monday evening, the 14th inst., was the president's inaugural address, on The Police Power and the Public Health, by John Sabine Smith, Esq.

The New York Polyclinic.—Dr. Francis J. Quinnan has been elected adjunct professor of rhinology and laryngology.

The New York Ophthalmological Society.—Officers for the ensuing year have been elected as follows: President, Dr. F. N. Lewis; vice-president, Dr. H. D. Noyes; secretary, Dr. F. D. Skeel; committee on admissions, Dr. Mathewson, Dr. Demott, and Dr. Roosa.

The Lying-in Hospital of the City of New York.—The new hospital building, on the corner of Second Avenue and East Seventeenth Street, was opened for the inspection of an invited company on Wednesday afternoon, the 16th inst.

Army Intelligence.—Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from January 6 to January 12, 1895:

De Smon, George D., First Lieutenant and Assistant Surgeon, will proceed from Fort Logan, Colorado, to Fort Douglas, Utah, and report for temporary duty.

Fisher, Henry C., First Lieutenant and Assistant Surgeon, is granted leave of absence for one month.

Lynch, Charles, First Lieutenant and Assistant Surgeon. The leave of absence granted him is extended one month.

Polhemus, Adrian S., Captain and Assistant Surgeon, is granted ordinary leave of absence for one month and fourteen days, in addition to the extension of leave of absence on surgeon's certificate of disability.

Robertson, Reuben L., Captain and Assistant Surgeon. The leave of absence for seven days granted him is extended twenty-one days.

Shannon, William C., Captain and Assistant Surgeon, is granted leave of absence for three months on surgeon's certificate of disability.

Naval Intelligence.—Official List of Changes in the Medical Corps of the United States Navy, for the week ending January 5, 1895:

Farenholt, Ammen, Assistant Surgeon. Detached from the U. S. Revenue Steamer Vermont and ordered to the Naval Hospital, Norfolk, Va.

Kindlerhoerer, C. P., Assistant Surgeon. Detached from the Naval Laboratory and Department of Instruction and ordered to the U. S. Revenue Steamer Vermont.

Cooke, George H., Medical Inspector, will attend, in addition to present duties, to officers on duty at Longue Island Navy Yard, but residing outside of the yard.

Society Meetings for the Coming Week:

Monday, January 21st: New York Academy of Medicine (Section in Ophthalmology and Otology); New York County Medical Association; Hartford, Conn., Medical Society; Chicago Medical Society.

Tuesday, January 22d: New York Dermatological Society (private); Medical Society of the County of Putnam (quarterly), N. Y.; Buffalo Obstetrical Society.

Wednesday, January 23d: New York Academy of Medicine (Section in Laryngology and Rhinology); New York Pathological Society; New York Surgical Society; American Microscopical Society of the City of New York; Metropolitan Medical Society (private), New York; Medical Society of the County of Albany, N. Y.; Philadelphia County Medical Society.

Thursday, January 24th: New York Physicians' Mutual Aid Association (annual); New York Academy of Medicine (Section in Obstetrics and Gynecology); New York Orthopedic Society; Roxbury, Mass., Society for Medical Improvement (private); Pathological Society of Philadelphia.

Friday, January 25th: New York Clinical Society (private); New York Society of German Physicians; Yorkville Medical Association (private); Philadelphia Clinical Society; Philadelphia Laryngological Society.

Saturday, January 26th: New York Medical and Surgical Society (annual—private).

Births, Marriages, and Deaths.

Died.

Balbridge.—In Huntsville, Ala., on Wednesday, January 9th, Dr. Milton C. Balbridge.

Hallam.—In Brooklyn, on Wednesday, January 9th, Dr. Albert Coburg Hallam, in his fiftieth year.

Hammann.—In New York, on Monday, January 14th, Dr. Elizabeth Hammann, aged twenty-eight years.

Lambert.—In New Orleans, on Tuesday, January 1st, Dr. Pierre Alexandre Lambert, in his eighty-seventh year.

Norbury.—In New York, on Sunday, January 13th, Dr. John F. Norbury, in his seventy-ninth year.

Semmes.—In Canton, Miss., on Wednesday, January 9th, Dr. A. T. Semmes.

Letters to the Editor.

THE PHYSIOLOGICAL RÔLE OF ANTITOXINE AND NUCLEIN.

To the Editor of the New York Medical Journal:

Sir: Inasmuch as the recent theories in respect to antitoxine inoculations are at variance with chemical and physiological laws, and, further, because they are not in accord with well-known physiological and clinical facts repeatedly brought to the attention of the medical profession during the past few years, I beg permission to direct the attention of your readers to the necessity of revising their opinions concerning the physiological rôle of antitoxine. Necessarily, this discussion will embrace a study of the function of nuclein in the animal organism, since antitoxine inoculations can not well be considered apart from nuclein medication.

Some years ago Professor Welch and Dr. Flexner, of the Johns Hopkins University, made a series of elaborate investigations to determine the rôle of diphtheritic poison in the animal economy. They first prepared attenuated solutions of the diphtheria bacteria which they injected into healthy rabbits, with the result that the animals died at the end of twenty-four
hours. In these cases some of the evidences characteristic of the diphtheritic poison were discovered on post-mortem investigation, but, as the time was so short, it is reasonable to assume that these evidences could not have been very marked. However, they took an equal quantity of the sterilized diphtheritic solution and injected it into other rabbits apparently in perfect health, and these animals died at the expiration of fourteen days, with all the characteristic evidences of diphtheritic invasion, although no bacteria were found. At these latter post-mortems it was found that marked changes had taken place in the kidneys, just as we observe in persons dead of diphtheria, and that there was fatty degeneration of the heart and liver, with more or less degenerative muscular changes; moreover, they found distinct indications of infiltration of the mucous structures throughout the body.

How does this evidence comport with the statement of Professor Henry Hun, in the present issue of your Journal, that "The injection of this serum is perfectly harmless; it can be injected in large doses, and exercises no influence on the temperature or on the kidneys or on the heart. There have been no unfavorable symptoms observed from its use?" In the same issue, Dr. J. Lindsay Porteous, who has had some unfavorable experience with the serum treatment, and is disposed to be conservative, says: "My own opinion, formed from a larger experience of the use of antitoxine, is, that a smaller dose should be given at a time, but given oftener, thus keeping up the antitoxine action continuously, and certainly reducing the pain of injecting a large quantity at once."

Has it never occurred to those who advocate the employment of so-called antitoxine that this substance is inappropriately named, and that it is, in fact, a toxine? It is certainly more of a toxine than the sterilized diphtheritic solution employed by Professor Welch and Dr. Flexner, because in preparing the diphtheritic solution for injection into the horse it must be exposed to the air in order to avoid sterilization. Such being the case, it must be apparent to the most casual observer that a medium of the toxine passes through the horse, and is finally introduced into the body of the patient suffering from diphtheria. Whether this infinitesimal attenuation supports the homoeopathic principle or not, I shall not stop to consider for the present, but that, through laboratory manipulation and subsequent introduction into the circulation of the horse, a true toxine is produced from a toxine is contrary to our interpretation of both chemical and physiological laws.

When we come to inquire into the rôle of antitoxine inoculations from either a chemical or a physiological standpoint, we are met with a problem exceedingly difficult of solution. Behring believes that the antitoxine inoculations contribute to the production of "defensive proteins," and that these defensive proteins, remaining in the blood serum, destroy the poisonos products resulting from diphtheria. It is upon this basis that we account for recovery from attacks of diphtheria as well as other diseases of microbial origin, or, rather, it might be said, where certain micro-organisms are known to be associated with disease processes. Roux, on the other hand, maintains that both immunity and cure are brought about through the increased cell resistance due to the introduction of the antitoxine, although no definite information is vouchsafed as to what particular cells are re-enforced—whether the nerve cells, the connective-tissue cells, the blood cells, or the epithelial cells.

Now, these explanations are exceedingly defective, because they are indefinite, but more especially because, in the practical adaptation of serum therapy, the methods of administration do not harmonize with chemical or physiological laws. It should be stated here, however, that the writer is not disposed to contend that serum therapy is not effective; neither does he wish to be classed with those who would undervalue the results that have been accomplished. The object of the present communication is to bring about a more rational view of this important form of medication, since it involves principles which hitherto have not been recognized; principles, too, which give fair promise of revolutionizing both our conception of disease and our methods of treatment. For example, according to Behring, quoted by Professor Welch, of Johns Hopkins University, part of a grain of blood serum obtained from a horse rendered increasingly protected against tetanus for a period of two years is sufficient to protect a mouse weighing three hundred grains (five drachmes). By a simple calculation this shows that the tetanus antitoxine is effective in the proportion of 1 to 9,999,900; or, in other words, that a single grain of this blood serum would procure immunity for, say, an animal like an ox or a horse weighing nearly fifteen hundred pounds. Again, antitoxine solutions are in the market which are stated to be effective in the proportion of 1 to 50,000, although it is now well known that corrosive sublimate, our most efficient antiseptic, is effective against spores in the strength only of 1 to 20,000. It is evident from the foregoing figures that the allegations of antitoxine can not be substantiated upon either a chemical or a physiological basis, and we must therefore seek elsewhere for an explanation of their modus operandi. If these antitoxines possessed a titre of the antiseptic properties alleged for them—using the word antiseptic in its modern acceptation—it would be impossible to produce the new remedy under any circumstances whatever, since its production in the animal inoculated would promptly kill it.

I now turn to a consideration of the chemical and physiological properties of nuclein, a phosphorized protein, probably the most effective of the "defensive proteins," a substance which is constantly produced by the multinuclear white blood-corpuscles in the human economy. Given a fairly well-nourished person with an attack of diphtheria, typhoid fever, or pneumonia, and we observe no alarming symptoms so long as nutrition is maintained by the usual methods. In diphtheria, barring septic infection by streptococcus, the remedies that have been heretofore employed have given fairly good results in private practice. As soon as recovery is established, there is no danger of immediate reinfection, simply because the toxine of the disease, gradually taken into the system, has so increased the functional activity of these white blood-corpuscles that infection can not take place. And yet, notwithstanding the statements which have been advanced concerning the antiseptic and germicidal properties of nuclein solutions in a very large number of instances, it seems doubtful if this agent acts either as a chemical or a physiological antidote to the diphtheritic or any other poison — as we now understand chemical and physiological action. The remarkably small quantity of nuclein required to counteract diphtheritic invasion or to arrest the progress of the disease, whether simple diphtheria or complicated by sepsis, effectually precludes this conception of its powers. Had this topic been considered by Headland, he probably would have told us, as he did about arsenic, that it was a catalytic, and produced effects by its mere presence in the human organism. The writer is of the opinion that nuclein, in addition to its antiseptic and germicidal properties, enacts the rôle of a ferment; and he is also of the opinion that the so-called antitoxine acts in the same manner. The very fact that antitoxine is an admixture of toxine with nuclein — produced in the horse by the presence of this toxine — is sufficient to account for its supposed virtues in counteracting diphtheria. This toxine, although infinitesimal, seeks the usual outlets of the body, while the contained nuclein, enacting the rôle of a ferment, contributes additional powers to the white blood-cor-
A FATAL CASE OF CHICKEN POX.

CLEVELAND, O., January 8, 1896.

To the Editor of the New York Medical Journal:

Sir: In the January 5th number of the Journal I read an article by Dr. Nisbet, taken from the Australian Medical Journal, which recalls to my mind most vividly a case very similar, occurring in my early experience, and for which I had found no parallel in medical literature until this case. Though very similar in many of its clinical aspects, the solution in my case is widely different, and challenges the propriety of entering the above-mentioned case on record as a death from chicken pox per se. I find on turning to my case-book for June, 1872, the following record, and memory recalls the case in all its details:

June 9, 1872.—Called to family of M. H. Find J. H., aged nine; H. H., aged seven and a half; S. H., aged five; M. M. H., aged two and a half; infant, aged one year—all in the eruptive stage of varicella. No symptoms calling for treatment beyond the ordinary dietetic restrictions and hygienic in-tructions were recognized, and, with the assurance that all would turn out well, the cases were dismissed.

12th, P. M.—I was recalled. Found all doing well save M. M. H., aged two years and a half. The eruption in his case was much more copious than at first visit, many of the pustules having developed into large vesicles with a tendency to become confluent, and contents somewhat dark. Temperature, 101.5°.

13th, P. M.—Vesicles increasing in number and size, and the surrounding area assumed a purpuric hue. Is restless. Takes plenty of milk. Temperature, 102°. Treatment supportive and analgesic.

14th, P. M.—Eruption more confluent, particularly on back and thighs, and multiplying on mucous surfaces, lips, buccal cavities, and pharynx. Is restless and refuses food. Temperature, 102°; pulse, 120.

15th, P. M.—Eruption more copious, and back, shoulders, and nates are one great blister filled with a purpuric serum. Of the vesicles on mucous surfaces, many are broken, and from their surfaces exudes a darkish serum. The submucous connective tissues of post pharynx are swollen and edematous; bowels are loose; stools copious and watery. But little food has been taken; there is some thirst. Still restless. Temperature, 101.5°; pulse, 115. Treatment is now and has been with iron, quina sulfate, and mineral acids, with camphorated tincture of opium enough to secure rest.

16th, A. M.—Patient passed a more quiet night than for several nights previous without much anaodyne. Large vesicles on back have opened, leaving large, raw surfaces, and the epidermis is hanging loose in large flakes, and the denuded surface is pouring out much purpuric serum, rendering a frequent change of napkins necessary. The edema of the throat continues somewhat aggravated. Patient rather inclined to somnolence, and asks for nothing; swallows with difficulty, and but little food or drink has been taken. Temperature, 98.8°; pulse, 99. Stimulants were ordered, but the trouble in swallowing prevented their use by the mouth, and they were given perrectum.

5 P. M., same day.—The somnolence of morning had now developed into somewhat profound coma. Patient taking no nourishment or medicine. Pupils, somewhat dilated, respond but sluggishly to strong light; respirations regular, slow, and almost puerile. Local conditions not much changed, except that the back presented a more purpuric hue, as did the sores on mucous surfaces. The general appearance of the body, where not eedynysed, was that of cyanosis. Temperature, 97.3°; pulse, 78.

It was very apparent that death would soon end the case, and the fact that I was about to lose a patient with or from chicken pox was very embarrassing to me in face of the fact that there was no precedent on record. The coma developed into profound stupor, and the respirations grew slower and noisier until 3.45 A. M. of the 17th of June, when he passed away quietly and without a struggle. I had recorded the death cause as chicken pox in case-book, and the only such case I had ever known. But I have since changed my solution of the case and modified the record. My little patient died, not from chicken pox, but from effusion or hemorrhage into the subdural and
arachnoidal spaces of the brain, and edema of the glottis resulting from the purpura hemorrhagica which complicated the initial trouble, chicken pox. I am content to leave this correction stand until I can conceive how uncompleted chicken pox can result in death. The striking similarity between my case and Dr. Nisbet’s, referred to, causes me to doubt the correctness of his conclusion as to the cause of death.

Nicholas F. Schwartz, M.D.

THE CASE OF MRS. MAYBRICK.
Dublin, January 2, 1895.

To the Editor of the New South Medical Journal:
Sir: You inserted some time since in your columns my letter to the Liverpool Review, in which among other things I objected to the medical evidence for the prosecution in the case of Mrs. Maybrick as not being purely medical. I was somewhat surprised to find this practically admitted and defended in the columns of one of the leading English medical journals, the Lancet. A physician, according to the Lancet, is quite justified in a case of difficulty in looking at the evidence of motive and the general surroundings of the case in forming his opinion as to the probable cause of death, and, I presume, in not telling the jury (unless asked the question) the grounds on which he formed it. This is a very serious question as regards medical evidence in criminal cases. The jury when listening to the evidence of motive and of the general surroundings of the case may imagine that they are hearing independent evidence confirming that of the doctors, when in reality they are hearing the grounds of the doctors’ opinions.

This, however, is not all. The medical witness for the Crown gives his evidence at a stage of the trial when the prisoner’s witnesses have not been examined. If he waited to hear them he might take a different view of the evidence of motive and the other surroundings of the case. But in fact he has not heard even the whole of the other evidence for the prosecution, and is dependent, not on sworn testimony, but on what has been told him by the relatives and friends of the deceased. One of the principal Crown witnesses in the Maybrick case not only derived his information from these sources, but obtained inaccurate information, as appears from his subsequent narrative in the Liverpool Medico-chirurgical Journal. When in attendance on Mr. Maybrick Dr. Carter states that he did not know that the deceased attributed the origin of his illness to an overdose of aperient medicine. Who told him that? The evidence went to show that the patient ascribed it to an overdose from a totally different bottle. Indeed, when Dr. Humphreys was called in, on the day after the overdose, Mr. Maybrick complained of constipation, and the doctor ordered parapaine-irinid as a mild laxative. There was no appearance of diarrhea for a week afterward. But arsenic was found in this bottle of aperient medicine, though it was not in the prescription. Hence some one who wished to fasten the crime on Mrs. Maybrick told Dr. Carter that her husband had ascribed his illness to that bottle; and this was evidently one of Dr. Carter’s reasons for concluding that Mr. Maybrick died of arsenical poisoning.

Again, I need hardly say that a fatal dose of arsenic would mean a much larger quantity in the case of a regular arsenic-eater than of an ordinary person. But when the medical witnesses for the prosecution were examined no evidence of arsenic-eating had been given, and indeed the evidence given at the trial on that subject was by no means so conclusive as it has since become. Therefore the doctors were ignorant of one of the most important “surroundings” of the case when they gave their evidence.

Dr. Carter, when asked why he fixed on the 3d of May (the day on which Mr. Maybrick forgot to take with him to his office the lunch which his wife had prepared for him) as the date of administering the fatal dose, gave this singular answer: “I had it on my mind.” Pressed further, he said: “I was told that he was unable to retain anything on his stomach for several days” (afterward). This was certainly an exaggeration, and the doctor did not mention the morphine to which his colleague, Dr. Humphreys, ascribed the vomiting.

I hope the medical profession on both sides of the Atlantic will press for a public inquiry. There seems no doubt that there is a letter from Mr. Maybrick himself to his brother Michael, containing full details of his malady, that has hitherto been kept back.

A Barrister

TABLES OF INTESTINAL OPERATIONS.

New York, January 5, 1895.

To the Editor of the New York Medical Journal:
Sir: Allow me to call your attention to the fact that in the January, 1895, number of the Annals of Surgery, in the course of some remarks on Gastro-enterostomy by the Murphy Button Anastomosis by this Method, by Dr. W. G. Mayo and Dr. Charles H. Mayo, there appears a table which, with a few omissions and inaccuracies, is substantially a copy of the table which appeared in connection with my paper on Intestinal Anastomosis read before the New York State Medical Association on October 11th last and published in your Journal issued December 1st.

F. H. Wiggins, M.D.

A WARNING.

1309 Third Avenue, New York, January 14, 1895.

To the Editor of the New York Medical Journal:
Sir: Let medical gentlemen in the city beware of a genteel, fluent-spoken man of middle age who desires the doctor to come down to the East River to examine the crew of a bark just arrived from Brazil as to their health. For this service the doctor is promised ample payment by the ship’s agents, as the ship came through the sound instead of passing quarantine, etc. Meantime the doctor is “braced” for a small loan, or the surroundings of his office are “taken in” by the stranger with the view to future robbery. I have been able to put several gentlemen on their guard within the last few days, as the “vend” is very ancient.

Thomas Latham.

Proceedings of Societies.

SOCIETY OF ALUMNI OF BELLEVUE HOSPITAL.

Meeting of November 7, 1894.

The President, Dr. C. C. Barrrows, in the Chair.

Suture of the Torn Cervix immediately after Labor.—Dr. W. R. Pryor read a paper with this title. (See page 71.) Dr. Graydon said that it had been his practice to sew up the cervix primarily, and, so far as he could recollect, he had secured none but the best results. On the removal of the stitches he had found uniformly good union, and had not found that he had overstepped the natural boundary between the cervix and the vagina; and he had not observed that this primary operation had interfered with the drainage of the lochia, or that it had caused sepsis; but he had found that the parts had healed well, and that his patient had been very grateful to him for
doing the operation at this time. It seemed to him that Nature would have made a woman with a split cervix if this was necessary to secure good drainage after labor. If there was a laceration of the cervix beyond the first degree, we were called upon, in his opinion, to repair that laceration just as we now repaired lacerations of the pelvic floor. In cases of hemorrhage due to a rent involving the circular artery, it was, of course, a necessary operation. Primary repair of the rent was not at all difficult if it was done in a proper manner. If we attempted to do it with the woman in Sims's posture, we should meet with difficulty, but if she was put into the lithotomy posture, and the parts were brought into view with a voiella, there would be no difficulty in inserting the sutures properly. It was easy to obtain good union, provided we did not introduce septic matter at the time of the operation. If we did this, we should not blame Nature for it, but only ourselves. If we took the precaution to tie the stitches tighter than in the secondary operation, we should be still more likely to get good union.

Many physicians condemned primary trachelorrhaphy because they did not tie the stitches tight enough, and failed therefore to get good union. While, therefore, the author might be right, and while undoubtedly the influence of a lacerated cervix on the uterus had been greatly exaggerated, he still felt that we were called upon as honest men to sew up the tear. If the operation was done in a proper manner, as already described, we could determine the limits of the tear, and introduce the stitches easily; we could then go home with a clear conscience, and we could in this way often avoid unpleasant subsequent criticism on our work as obstetricians by gynecologists and other fellow-practitioners.

Dr. J. Clifton Edgar said that about two years ago he had occupied about the position taken by the last speaker, but he had had since then an excellent opportunity of studying, in hospital, the repair of the lacerated cervix. He would like to give the history in outline, and exhibit the photographs of a case, the latter taken ten days after the operation. The patient had been a primipara, twenty-four years of age, who had been admitted last spring into the Emergency Hospital. The labor had begun at midnight of May 16th, and the child had been born at nine o'clock the next morning. As far as could be found out there had been no interference with this labor, except that the physician in charge, feeling that the membranes had ruptured rather early, and that the second stage of labor had been rather prolonged, had used compression of the fundus before the cervix had been fully dilated. This would seem to explain the bilateral laceration of the cervix. Immediately after the birth of the child the blood had come away in gushes. The placenta had been expelled, but the blood had continued to come in spurts. Examination had shown a laceration on one side, up to or beyond the vaginal junction, and a lesser laceration on the other side. The bleeding had been controlled by iodoform gauze. The patient had nearly collapsed from loss of blood, but had rallied promptly under the usual treatment. The speaker said that he had not seen her until eight hours later. At that time, she had had a fair pulse, and there had been some slight oozing from the vagina. The gauze had been removed and he had determined to perform primary trachelorrhaphy, using No. 3 cutout. Five small strips of iodoform gauze had been subsequently placed in the os to keep the canal open. The child had weighed about eight pounds. The perineum had been practically normal. On the evening of the day of the operation she had had a temperature of 100°2, the next day 100°3, and from that time on the pulse and respiration had been practically normal, and the temperature had fallen to the normal point. The patient had been discharged from the hospital on May 30, 1894. No douches had been given after the operation. So far as could be made out from the history, the lochia had been normal. The photograph showed a rather large cervix and excellent union of the torn parts. The interesting feature of the case centered upon the involution, which had been poor. The uterus had been large and flabby at the end of eleven days. There might have been other factors in the case besides the primary trachelorrhaphy, but it had seemed to him that this was the probable explanation of the incomplete involution.

Dr. Robert A. Murray said that he believed that all the points mentioned in the paper could be answered in a very different way from that adopted by the author. Some years ago he had himself read a paper on primary trachelorrhaphy, and had drawn his conclusions at that time from the cases in which he had operated because of hemorrhage. His first three operations had been done without any assistants, and with the ordinary materials found in a pocket case. The result had been absolutely perfect in these particular cases. He felt that the only lacerations which were to be sewed up were those which were quite extensive, and where there was hemorrhage or danger of its occurrence. It was his practice to repair a perineum, not only to restore the anatomical relations, but to prevent the patient from becoming septic. If sepsis could be a factor outside the vagina, why should it not be inside the vagina? It had been contended that primary trachelorrhaphy subjected the patient to additional risk of sepsis, but it should be remembered that if the tear was left ununited there was danger of septic material being absorbed. It should also be remembered that the passage of the lochia, over these lacerated parts prevented them from healing, and this was true no matter how carefully and frequently the patient was doused. Indeed, he had been inclined to think that douching actually interfered with healing.

He spoke with confidence on this point because for years in the Maternity Hospital it had been the practice to give douches, and since that practice had been discontinued the union in these cases had been just as good as formerly, if not better. In the primary operation the tissue would always be found edematous and relaxed, and this would facilitate the operation of trachelorrhaphy. Unless the cervix was weakened, it would distend rather than tear. He preferred to use a tenaculum with only one point, for with this instrument it was very easy to hold the uterus in position, even though the hemorrhage was so great as to prevent the guiding of the manipulations by vision. He had on several occasions demonstrated the fact that one could pull the cervix down to the vulva without making unsafe traction, and without using a Sims's speculum. He preferred to pass the sutures with a curved needle. The material for suturing should be of such a nature as not to be softened by the constant flow of lochia over the parts; hence he would always use silver wire or silk-gut gum. If the cervix was properly repaired there could not possibly be any more interference with drainage than if no laceration had occurred. He recalled very well the author's having advocated the introduction of iodoform gauze to stop hemorrhage. Was there any more risk from sewer up the lacerated cervix than from inserting the gauze? He had seen two women lose their lives because they had not been subjected to the primary trachelorrhaphy. One of the cases had been a right occipital posterior position at the Maternity Hospital, in which the forceps had been applied, and in which free hemorrhage had occurred after delivery notwithstanding a very firm tampon in the vagina. When he had been called to see this patient he had removed this tampon, and had found and secured a spurting blood-vessel, but the patient had died in about six hours. In another case, in which he had first seen the patient in a moribund condition, she had been treated in the same way, by tampon, and had died. This had made a
profound impression on him, and rather than make any such mistake, he would prefer always to sew up the tear in cases of severe hemorrhage of this kind. Since then he had made it a rule in the hospital to sew up the tears in the uterus, and he thought there had been less subinvolution, and that the women had been able to leave the hospital sooner and in better condition than before. No matter what the skill of the obstetrician, tears would frequently occur; no obstetrician should be blamed for lacerations, but he should be blamed if they were not repaired.

Dr. W. Evelyn Porter said that he differed very radically with the reader of the paper. If the patient was given a hot douche and a dose of ergot after delivery, the internal os would be so well defined as to map out the limits of the uterine structure, particularly if the parts were drawn down into view, Dr. Pryor had limited the operation of primary trachelorrhaphy to hemmorhage, but he had not stated the degree of hemorrhage which he would consider to be a proper indication for this operation. The speaker's own practice had been to apply an ordinary aseptic pad, after giving a hot douche and ergot, and then to wait for a few minutes; if there was any considerable hemorrhage, he resorted to this operation. If in the course of the labor he had reason to believe there had been much laceration, even though there was not much hemorrhage, he would still resort to the operation, especially in view of the many cases of inflammatory disease and epithelium of the cervix found in persons who had suffered from unrepaired cervical lacerations. The danger of the operation in the hands of the aseptic surgeon would be practically nil, and he thought that the difficulties of the technique had been greatly overestimated by the author. In cases needing perineal sutures as well, he preferred catgut for the cervix; otherwise silver wire or silk-worn gut was better. He thought that if Dr. Edgar had used douches, ergot, and subsequently quinine, he would not have observed this subinvolution in the case reported by him. The President said that he had long been interested in this subject. About five years ago he had read a paper in which he had reported nine cases of primary trachelorrhaphy. Since that time he had continued to close all important lacerations of the cervix immediately after labor. Where there was a large number of small lacerations, requiring so many sutures as to strangle the tissues, he would not suture them. He had never seen any failure of union, or any serious result, and he had never experienced the slightest difficulty in inserting the sutures. He believed that there were many cases of laceration of the perineum which should not be sewed up— as, for instance, where there had been a great deal of contusion of the parts. Such a condition did not exist as a rule in the cervix, hence he sewed up the lacerated cervix more frequently even than the lacerated perineum.

Dr. Pryor said that, in the absence of hemorrhage as an indication as to how deep to pass the suture, he would be at a loss in most cases to know just what tissues should be united. He had done the operation a few times for hemorrhage only. The slighter degrees of bleeding were much better controlled by pressure. He could not say that he had seen cases made septic by sewing up the cervix immediately after labor, but he thought this might very easily occur. Civilization required that the average woman should marry many years after the establishment of the menstrual function, and come to her first labor with an hypertrophied cervix. After the puerperium, he believed in subjecting the cervix to amputation just the same as any other hypertrophied cervix which was found in sterile women. He objected especially to the introduction of another meddlesome operation into obstetrics, where already too little was left to natural forces.

**Book Notices.**

The author's experience as a practitioner and teacher of midwifery has suggested to him the desirability of a book that would give its reader more definite guidance in practice than is to be obtained from the average text-book. He has endeavored in this volume to indicate clearly the best way of dealing with each complication of labor, and he gives his reasons for such indications. He starts with the premise that labor is natural when the mother is in good health and the pelvis is of not less than normal size; when the child is living and of not more than normal size; when the vertex presents, and the child's back is in front; when the membranes do not rupture until the os is at least of three quarters its full size; when the placentia is implanted above the lower segments of the uterus, and is not detached until the child is born; and when uterine contractions and retraction go on at such a rate that the child is born within twenty-four hours from the beginning of the labor pains, and continue after the child is born. If these conditions are fulfilled, the patient would do as well without a doctor as with one, but it can never be foretold that they will be. So he describes in a clear, practical manner the various factors that produce difficult labor, and details the methods that must be employed to relieve them. The work is well written, and it is likely to prove useful to all students and practitioners of obstetrics.

The editor of this work has taken advantage of the appearance of a new edition to add a chapter on sexual erethism. The latter he considers either reflex, in consequence of peripheral or central irritation, or psychical, and he lays stress on the necessity of distinguishing these causes that are abnormal and pathological. Such patients he does not class with sexual perverts, of whom he says that, while a certain proportion would gladly be free from the chains that bind them and are eager for help, the larger proportion are as morally depraved as the followers of any other form of vice.

Unpleasant as these persons may be to the physician, there is no class to which he can render greater assistance, if judicious in his treatment and advice, than to the sexual neurasthenic.

The authors state that this volume is intended for those who, without any previous knowledge of the subject, desire to begin the study of physiology. They have purposely written it in an elementary and didactic manner, in order that it may
serve as an introduction to more advanced manuals, such as Professor Huxley's *Elementary Lessons in Physiology*.

While Professor Foster has supervised the work, and acknowledges his responsibility therefor, Dr. Shore is the principal author. The latter has based his instruction on the principle that has made his collaborator's teaching so successful—that of actually observing and studying physiological phenomena as far as is possible. The material required and the methods of investigation are plainly described, and there can be no excuse for neglecting such practical studies.

The scope of the work includes the physiology of the blood, the skeleton, the muscles, the circulation, the respiration, the digestion, the spleen, the kidney, animal heat, the nervous system, sight, hearing, and speech.

The book is an excellent work for use in high schools and colleges.

This volume is divided into two parts, the first devoted to a consideration of pus, the second treating of suppuration. The author has successively grouped the macroscopic, histological, and chemical characters of pus, a knowledge of which is essential to comprehend the features of suppuration. The pathological anatomy of supplicative lesions, their aetiology, with particular reference to pyogenic microbes, and their pathology with reference to pyogenic substances, are discussed with sufficiency and clearness. A final chapter is devoted to the general pathology of pyogenicness.

The book is written with the completeness characteristic of the accomplished author, and it is one of the most valuable monographs that have appeared in this series.

The fourteenth edition of this work scarcely calls for notice, for no better recognition of its value could be mentioned than a statement of the number of editions in which it has appeared.

Those who have followed the author's valuable papers that have appeared in the *Edinburgh Medical Journal* between October, 1891, and May, 1894, as well as those that have read various abstracts of these papers published from time to time, will gladly welcome the more permanent form in which they now appear.

The first part of this volume includes the papers on the functional disorders of the vocal mechanism, the second part treats of the development of speech and the developmental derangements, and the third part is devoted to speech in its relations to diseases of the nervous system. Each of these subjects is considered at length, and the text is illustrated with numerous diagrams and woodcuts. An appendix has been added containing the notes on three cases of speech disturbance and a reprint of a graduation thesis on the physiology of the larynx.

The volume is a useful addition to the literature of speech disorders.

This volume gives the data relating to the existence of infectious diseases in Budapest during the decade 1882 to 1891, and the statistics for almost eleven months of the year 1881. The diseases included in the list are typhus and typhoid fevers, measles, variala, scarlatina, diphtheria, and grippe. The reasons for the prevalence of each of these diseases are discussed, and their monthly prevalence during the service of years is indicated by a graphic chart that must have involved much labor.

Tables are also printed of the daily barometric register and the reported cases of infectious diseases. The volume is a valuable one to those interested in this important subject.

**BOOKS, ETC., RECEIVED.**

Bromide of Ethyl.—The Boston Medical and Surgical Journal for December 29th contains an article on this subject by Dr. Charles Greene Cumston, in which he remarks that it is very important not to employ the bromide of ethylene, as it is a very toxic substance, only slightly volatile, and a bad anesthetic. The bromide of ethyl, however, is a very volatile liquid, its boiling point being 110° F. It burns with difficulty, and its density is 1.40. When ready for administration, the liquid should have the following properties: 1. It must be extremely volatile; when poured on the hand, it should evaporate completely and rapidly without leaving any deposit. 2. It must be colorless; if it is of a yellowish color, it is decomposed, and a little bromine has been set free, which would irritate the respiratory tract. 3. Its odor must be sweet and ethereal.

The purity of the drug depends on the mode of its preparation and on the manner of preservation. The only correct way of preparing it is “by decomposing alcohol of wine by sulphuric acid in presence of bromide of potassium, and afterward rectifying it by distillation on oil of sweet almonds.” Light, dampness, and contact with air decompose it, and it should be kept in tubes hermetically closed with a flame.

Narcosis by this drug is similar to that of chloroform; both act on the brain, then on the medulla, and lastly on the bulb. Chloroform chemically irritates each center before it paralyzes it, but the bromide acts directly; consequently there is no excitement, and no hysteric reflex is to be feared. It is also a vasodilator; it produces congestion of the head, and thus no syncope is to be feared, even if the patient is in a sitting posture—so necessary in certain operations on the throat.

The dose of bromide of ethyl varies according to the age of the patient. In children, the author employs from a hundred and eighty to two hundred and twenty-five grains; for children over twelve years of age and for adults, from two hundred and twenty-five to three hundred and seventy-five grains may be given, according to the constitution of the subject. The patient should be ordered emphatically to take nothing to eat, not even a glass of milk, on the morning of the operation. The mask should cover the mouth and nose perfectly, and no air be allowed to enter; on this point the author insists. The entire dose should be given at once. A period of from twenty to thirty seconds is sufficient in which to produce sleep, and the operator should be ready to begin as soon as narcosis is complete. The insensibility lasts from two to three minutes, sometimes a little longer. When narcosis is complete, the mask should be removed, and under no consideration should it be applied again.

All short minor operations can be done during narcosis with this drug. Superficial tubercular glands can be removed, abscesses opened, etc. Narcosis with this drug is particularly eligible when an examination of the pelvic organs is to be made or a pessary introduced, as it completely relaxes the abdominal muscles, thus permitting of easy palpation. No disagreeable odor remains in the room, and the patient may enjoy his breakfast without nausea or headache.

Dr. Cumston gives the following rules as to the administration of this drug: 1. Bromide of ethyl should be carefully distinguished from the bromide of ethylene. 2. Employ only a pure and, if possible, a freshly made preparation. 3. Give the drug only en masse, as some patients have died from small and continued doses. 4. Do not prolong the administration over one minute. 5. Once the mask is removed and the operation begun, do not apply the mask again. 6. The contraindications are dangerous lesions of the heart and lungs, as well as of the kidneys.

A Method of Trephining.—The January number of the Edinburgh Medical Journal publishes an article by J. M. Cotterill, M. B., F. R. C. S., Ed., in which he remarks that the plan adopted for some years past of replacing the whole discs of bone removed by the trephine or of cutting up the discs into several fragments and planting these over the exposed surface of the dura mater is open to objection. The various heterogeneous methods also have, he says, scarcely justified their existence, for the results are insufficient and frequently very unsatisfactory. Any plan, then, which will admit of free access to the brain without the disability of a large actual or imperfectly closed opening in the skull would appear to be very desirable. Various modifications, says the author, have been proposed by Bruns, Toison, and others, but none of them appear to him to be simpler or more effectual than the plan which he had used before studying their methods, and that he describes as follows: 1. Select as the base of the proposed flap a part of the scalp carrying large vessels, e. g., in front the supra-orbital, at the side the temporal and its branches, and posteriorly the occipital. 2. Make two small V-shaped incisions corresponding to the lower ends of the Ω-shaped incision, their angles looking toward each other. Carry these incisions down to the bone and strip off the pericranium from a surface of the skull of about the size of a sixpence. 3. Apply a half-inch trephine at each of these points, and take out the two small discs of bone. 4. Pass a periosteum-scraper from one of these two trephine openings to the other between the pericranium and the skull, making a little tunnel. 5. Pass a fine saw (metacarpal) along this tunnel, and saw through the neck of bone lying between the two trephine openings, cutting down only to the level of the inner table. This can easily be done, as the difference between sawing the diploe and sawing the inner table is quite palpable. If necessary, a curved director may be passed under the bone to
The author prefer to do this part of the operation first, as he finds that one is much less likely to disturb the relation of the flap of the soft parts to the bony flap than if it is done at a later stage in the operation. 6. The Q-shaped incision through the scalp is then completed, the flap being made of any size or shape that may be thought necessary. The pericranium is divided all around this line of incision through the scalp, great care being taken not to dislodge the soft parts unnecessarily from the bone. 7. The circu- lar saw is then applied around the circumference of the bony flap to be lifted up, and the saw should be applied obliquely from without inward, at the expense of the outer table, so that when the window of bone is replaced, it may be prevented by the projection of the inner table from sinking below the level of the rest of the skull. Although not absolutely necessary, it facilitates the use of the saw in getting around the corners, to take out two small discs of bone with the half-inch trephine at the upper angles of the flap. It may appear to complicate the operation to have to make four trephine openings, but, as a matter of fact, a half-inch trephine makes a very small hole, and perforates the skull very much more quickly and easily than a larger instrument. 8. The flap of bone is then gently lifted up with four elevators, and the inner table will be found to crack across at the neck with absolute precision along the line at which the outer table and diploe have already been divided with the saw. The flap of bone being held back, the dura is, if necessary, opened in the same direction as the rest of the incisions, sufficient edge being left to enable the operator to stitch it back into position when the operation is over.

In the cases in which the author has performed this operation the flap of bone has united satisfactorily, and firm union, partly fibrous, partly osseous, has taken place all around the line of incision, while there has been absolutely no roughness on the inner surface, and at post-mortems there has not been found to be any adhesion of the dura to the skull opposite the incision—a most important point.

This form of operation, says the author, is not applicable in every case of trephining. It is only of use where a large opening must be made in the skull for purposes of diagnosis or for the removal of large cerebral tumors or diseased portions of the brain. It might also be useful in dealing with intracranial haemorrhage, as it would probably afford better access to the wounded vessel than the old operation. Where it is found that the first flap of bone lifted up does not give sufficient room for the removal of the tumor, etc., there is nothing to prevent a second flap from being taken up in a similar manner from the lateral aspect of the original opening. The operation, says Mr. Cotterill, is neither tedious nor difficult. The first time he performed it, the patient was off the table in thirty-five minutes from the beginning of the operation.

The Treatment of Diphtheria with Antitoxines prepared without the Aid of the Animal Organism.—The Gazette hebdomadaire de médecine et de chirurgie for December 15th publishes an article on this subject by Dr. G. A. Smirnoff, of St. Petersburg. The researches of late years, he says, relative to the antitoxic properties of “vaccinated” animals have left the question of the modifications which the serum undergoes under these conditions an open one. One may ask, he says, if the elaboration of toxines is accomplished according to ordinary chemical laws, and may, in consequence, be effected without the aid of the animal organism, or whether it is a question of a strictly biological phenomenon the reproduction of which, independently of the animal organism, will be impossible. While the majority of authors believe in a strictly biological process, Emmerich, Tsuboi, and Locw have found that the bactericidal properties of the serum from “vaccinated” animals are in the albumin and not in the globulin. Tizzoni and Cattani also have found that the properties of the antitoxic serum are in the albumin and not in the globulin of the antitoxic serum. As, in a general way, the processes of biological chemistry are subject to the ordinary laws of oxidation, of decomposition, and of re-constitution, Dr. Smirnoff undertook a series of experiments in order to see if it was not possible to confer therapeutic properties on ordinary serum by submitting it to the action of chemical bodies.

The first experiments, which consisted in submitting the serum to a process of oxidation and afterward injecting it into animals, gave distinctly negative results. In rabbits this serum did not provoke any general reaction or any rise of temperature. In other experiments the serum was subjected to electrolysis, and more encouraging results were obtained. When a certain quantity of dog serum was subjected to electrolysis the first phenomenon observed was the formation of gas around the two poles. But, while flocculi of albumin formed in the tube which inclosed the negative pole, and the liquid became turbid, the serum in which the positive pole was plunged remained clear and transparent, and no albumin was precipitated. Under the continued application of electrolysis the flocculi of albumin that had formed around the negative pole became dissolved. If the reaction of the liquid is examined at this moment, says the author, it will be found that it is very acid around the negative pole and very alkaline around the positive pole.

The injection of electrolyzed serum, of alkaline serum, or of acid serum does not provoke any reaction in rabbits. But, if the acid serum is neutralized in such a manner as to give it a feeble alkaline reaction, or if a small quantity of acid is added to the alkaline serum, it will be found that the two, in subcutaneous injection, provoke a very distinct reaction. The alkaline serum, as well as the acid serum, in a dose of a cubic centimetre produces in rabbits an elevation of temperature which begins from two to three hours after the injection and reaches its maximum, 104.9° F., from five to six hours later. Animals injected with this serum do not show any other morbid symptoms.

Ox serum treated in the same way produces the same symptoms as the dog serum does, but the elevation of temperature that it provokes is less pronounced.

In order to ascertain what part of the serum the thermogenic action was attributable, Dr. Smirnoff made a series of experiments with ox serum deprived of its globulin. As the liquid obtained, which contained albumin, was deprived of its salts, the author added a solution of sodium chloride until the liquid contained 9° per cent. of the chloride, and then submitted it to electrolysis. The aced serum was then alkalinized and the alkaline serum acidulated, and an injection of each was administered to rabbits. The action of this serum deprived of its globulin was the same as that of the dog serum that had been simply electrolyzed. The check experiments made with a solution of globulin that had been subjected to electrolysis gave completely negative results. This showed, then, that the thermogenic properties of the serum after electrolysis were dependent on the modifications that the albumin had undergone, and confirmed the opinion held by Emmerich, Tsuboe, Cattani, and Tizzoni.

With regard to the curative or “vaccinal” properties of electrolyzed serum in certain cases of experimental infection, says the author, the researches made in this direction on animals infected with anthrax, diphteria, and with rabies gave completely negative results. But, as the preceding experiments showed that electrolysis acted, above all, on the albuminoid substances, Dr. Smirnoff questioned whether it was not possible to transform by the same method the toxines de-
developed in the serum into antitoxines, and, in order to settle this point, he made some experiments with diphtheritic cultures grown on the serum, on a solution of albumin, and on a solution of globulin. He was able to ascertain at first that the bacilli became very well developed in the serum and formed extremely active toxins of such a nature that five cubic centimetres of a culture fifteen days old was sufficient to kill a guinea-pig in from twenty-five to thirty hours. The toxins of the albumin cultures were less active; the globulin cultures appeared to be entirely deprived of toxins, and the bacilli themselves lost all their virulence at the end of a certain time.

The experiment had then been made only with serum and albumin cultures that had been subjected to electrolysis in the same way as the serum, and the liquid around each pole was brought to a feeble alkaline reaction, as in the preceding experiments, then filtered and injected into the animals. It was then ascertained that the cultures lost a large part of their toxins under the influence of electrolysis. For instance, a rabbit that had been injected with five cubic centimetres of a culture a month old died at the end of seventy-two hours, while another rabbit injected with the same quantity of the same culture that had been previously electrolyzed for six hours, survived after presenting gangrene of the skin at the point of injection.

Experiments on rabbits infected with virulent cultures and treated by injections of dialyzed cultures immediately, or two or three hours after injection, showed that the dialyzed cultures possessed very marked curative properties, whereas the test animals succumbed regularly to diphtheritic infection. The animals treated with electrolyzed cultures either survived or died much later than the test animals.

In order to ascertain whether the variability of the results did not depend on the fact that the toxins of the serum and the albumin cultures—and consequently the antitoxines which they produced under the influence of electrolysis—were less active than the toxins made in bouillon, the author made some experiments with cultures on bouillon which he afterward subjected to electrolysis. Rabbits were infected with virulent diphtheritic cultures, then, when at the end of twenty-four hours the first symptoms of infection appeared, an injection of from eight to ten cubic centimetres of a dialyzed culture was made. Under these conditions one injection often sufficed to bring about recovery at the end of several days. In a general way, says Dr. Smirnoff, it was ascertained that it was better to inject in the beginning a strong dose of an electrolyzed culture than to treat the infected animal with repeated injections of small doses.

**Bicycling for Women.**—Dr. Robert L. Dickinson contributes an interesting article on this subject to the January number of the *American Journal of Obstetrics*, in which he says that among the most difficult questions which present themselves daily is the problem of prescribing exercise. So unwise is the average woman to exercise that muscle work for its own sake presents none of the delight and afterglow which men usually get from it. To her the gymnasium often means dull routine; the bowling alley means broken corset bones under a one-sided, sudden strain; dancing is done in a bad atmosphere, in unsuitable dress, during sleeping hours; and horseback-riding, especially at a trot or with the close seat, is a jolting of the pelvic organs, with their supports stretched tight by the snug corset that the tailor-made habit demands. Only the summer presents, in the various sports, a means for the development of muscular energy whereby much good may be accomplished.

Riding, says the author, has certain advantages over the present style of horseback-riding. The fashionable conformed seat does not develop the body symmetrically, although, when women get into the habit of riding part of the time with the stirrup on the right side and part of the time with the stirrup on the left side, one objection to the spinal rotation and the asymmetrical development will be overcome. However, he thinks that cheapness, safety, accessibility, and the small amount of preparation required are in favor of the wheel, in a greater degree even for women than for men.

With regard to the sewing machine, the question has often been asked why women are advised to ride the bicycle while they are warned against the sewing machine. Dr. Dickinson thinks that the conditions under which the two forms of exercise are taken vary radically. A woman at the sewing machine, he says, must stoop to focus her eyes accurately on her work, and such a posture in the corseted woman brings with it a pressure to bear on the pelvic contents by means of the lower part of the pelvic floor. This is illustrated in Dr. Dickinson’s article by a cut showing the pelvic inlet nearly horizontal, and pressure from the corset steel gaining free access to the pelvic organs. The action of the legs also is a distinctly constrained one, and the indoor motion is a series of very short excursions in rapid succession, while the road machine calls for a full, slow sweep of the whole leg. If a woman rides a bicycle, stooping well forward while dressed in a snug corset, with her saddle far back, so as to be obliged to thrust forward on her pedals, the conditions are somewhat analogous to those under which she works at the sewing machine. She should wear loose clothing and sit upright, so that her weight is borne largely upon her tuberosities, with a level saddle fairly well forward; then the thrust is chiefly downward, the increased intra-abdominal pressure is lacking, and all the objectionable features are eliminated, except the proneness to excessive indulgence. The effect on the circulation will be that of any general exercise; therefore the pelvis will undoubtedly be subjected to a much-increased rapidity of circulation, and the whole of the pelvic floor and the organs above it will receive a well-defined stimulus, and by degrees a permanently increased tone, from regulated riding.

In bicycling there seems to have been found at last, says Dr. Dickinson, a form of outdoor muscle work which attracts women and entices them to many hours in the open air. It possesses all the advantages of walking or climbing, and it exercises a large number of muscles; therefore it seems to the author that there is no single exercise that will so efficiently develop muscular tone in the pelvic floor as this. Dr. Dickinson cites some cases illustrative of this, and gives a cut with two tracings from the same patient showing the difference of her profiles with and without a loose corset. Nearly all the objections to the use of the corset raised by medical men involve the supposition that whatever straining the pelvic contents are subjected to must necessarily be under a snug corset and with the woman bending forward. It has been seen that these are distinctly hurtful conditions, although, says the writer, some women do not have suffered no harm from it. To direct, however, that the corset should be taken off, leaving a narrow girdle of pressure, does as much physical harm as it does good, and to replace the corset by a health-waist is to make an improvement of relatively small value, although the rigid front steels, the most harmful factor in the corset, will be banished. The author is convinced, from his own studies, that the health-waist should not be countenanced except as a temporary expedient where the breasts are large or flabby.

There has been made, he says, a very grave objection, which, if well founded, should induce us to be exceedingly cautious in suggesting this exercise. It has been said to begat or foster the habit of masturbation. It is perfectly conceivable that under certain conditions this habit could be engendered,
but, if the rider sits upright and has her saddle moderately tight and fairly level, the weight rests upon the buttocks, and there is anatomical reason to believe that this posture will diminish erotic tendencies, and that with proper precautions there is very slight danger of the habit being started or fostered.

Under proper conditions of costume and posture, with care that the exercise is increased gradually and properly graded for individual cases, and where there is no acute inflammation to contraindicate it, bicycling will probably show itself capable of large results as an agent in curing pelvic disorders, since it is one of the few exercises which attract women. It seems hardly too much to say, says Dr. Dickinson, that the promise from the bicycle is far-reaching. Through it and the habit it engender we may look for better and freer dress and shorter dress in bad weather, for better exercise, for out-of-door activity, for steadier nerves, for stronger muscles, for painless periods, and for easy labors.

The Newer Antipyretics; Acetanilide and Phenateine; their Drawbacks.—The British Medical Journal for December 22d contains an editorial on this subject in which the writer says that, although acetanilide is one of the most efficient antipyretics, it is not altogether free from the objections attached to other drugs of the aromatic series. It induces symptoms of intoxication more frequently, perhaps, than any of the others, and they are at times more alarming. Its action on the nervous system is similar to that of antipyrine, and its power of lessening pyrexia is even greater. The fall of temperature is usually accompanied by a more or less profuse perspiration, and it may attain its maximum in two or three hours and finally bring on depression and collapse; sometimes a rebound is ushered in with chilliness and rigor. On the other hand, says the writer, a few reports show that this drug, like antipyrine, may send the temperature up in an unexpected way; its action on the heart may be very pronounced, and the utmost care is necessary in its administration to children and weakly individuals. There is a difference of opinion as to whether the depressive action attains the same degree as that following the employment of antipyrine. With the exception of miliaria produced by copious diaphoresis, bad effects on the skin rarely show themselves. An impression exists that acetanilide may induce or increase bronchial catarrh in children, although there is no evidence that it does so in greater measure than antipyrine; cyanosis is, however, more striking, as it may appear as the result of very small doses and persist for days after the use of the drug has been discontinued. Its prolonged administration, even in moderate doses, may give rise to a decided state of anemia; the onset of this is often rapid and it may reach a considerable degree. Gastric disturbance is not prominent, impaired appetite and nausea being only occasionally noticed.

The doses of acetanilide as an antipyretic vary from five to ten grains for an adult; for a child three years of age one grain may be given, and for children from ten to fifteen years of age the dose is from three grains to four grains and a half; it should generally be combined with a stimulant. Its power as an analgetic is slight.

With regard to phenacetine, says the writer, its freedom from ill effects has been somewhat justified by experience; nevertheless, we may meet with unpleasant and profuse diaphoresis, rendering its habitual use in phthisis and typhoid fever undesirable. Collapse and exhaustion are not unknown even after moderate doses, while palpitation and oppression of breathing followed by nausea and vomiting have also been observed. Cutaneous eruptions, chiefly urticarial, prevail with a frequency scarcely inferior to that observed in the employment of antipyrine, and cyanosis of the face, due to changes in the hemoglobin, may be seen in a similar degree. Its use as an antipyretic remains small, as its power in that respect is not equal to that of the others, except when it is employed in doses that very often give rise to toxic symptoms.

The important question of impurity and adulteration should not be lost sight of in considering the ill effects of any drug. Many of the toxic symptoms of acetanilide so closely resemble those of aniline poisoning as to suggest the production of that substance in the blood. There is a close relationship between the two bodies, and there is therefore some ground to suspect the occasional presence of aniline in samples. Phenacetine may be adulterated with phenetidine, a poisonous substance which, in small doses, brings on kidney trouble.

The question of antipyrine hinges largely upon the important fact that a persistence of high temperature implies serious consequences to the heart muscle; on the other hand, we gather from clinical evidence that a fall in pyrexia is followed by marked relief of the patient’s general condition. An ideal antipyretic, according to Liebermeister, says the writer, would be one that limited the production of heat, and it is alleged for the antipyretic group that such is their action, “repressing thermogenesis and simultaneously rendering heat dissipation more efficient.” Gottlieb urges that an antipyretic of the antipyrene group should be given when it is desirable to procure a reduction of high temperature rapidly and safely, and to reserve quinine (which, he holds, lessens heat production and is a true antipyretic) for a more prolonged administration. To some extent, says the writer, the therapeutic application runs upon the lines of this generalization, for quinine continues to be the febrifuge most favored in the hectic state, and antipyrene and acetanilide may be reserved for sudden accessions of temperature of short duration. The prevalence of heart failure among the ill effects of the antipyrene group enjoins the necessity of caution where the cardiac organ suffers. The study of the ill effects of drugs is of great importance to therapists, and much can be done in the way of prophylaxis if they are kept prominently in view. Perhaps in the future they will receive increased attention, and something may be done to establish the employment of antipyretics on a more definite basis.

The Academy of Stomatology, of Philadelphia, a new association of dental practitioners, has been organized for the purpose of investigating and studying all matters connected with the mouth, its functions in health, and their aberrations in disease. The academy, we learn, already numbers among its members a majority of the most active and advanced dentists of Philadelphia, men who have the best interests of dentistry at heart, and who energetically forward the work of dental professional progress to the best of their ability and means. The academy has secured a handsome suite of rooms for its exclusive use in the holding of its meetings, clinics, etc. In connection with these a dental library and museum is being established, together with a reading room, where it is proposed to keep on file all the leading dental periodicals of the world. The reading room and museum will be open to members at all times during the day and evening, and it is expected that the facilities thus offered for consulting the periodical literature of dentistry will be largely patronized by the profession of Philadelphia and vicinity. The ultimate purpose of the academy is to establish a library and museum related to stomatology which will be consulted by dental practitioners throughout the entire country.

The New York Academy of Medicine.—At the last regular meeting, on Thursday evening, the 17th inst., the validating
An American View of the Medical Department of the British Army.—The British Medical Journal for December 29th contains a notice of an abridgment of Lieutenant-colonel A. A. Woodhall's report on the medical department of the British army as observed by him in 1891. The Journal says: "The abridged report, extending to one hundred and sixty pages, is so comprehensive that we can form some idea of the elaborate character of the full official report; indeed, the abridgment is such an admirable summary of the organization and regulations of our army medical department that it might be perused with advantage by the medical officers themselves; every point almost is reviewed with surprising accuracy, and any misstatements are of the most trifling character."

"We have always been struck with the general excellence of reports issued by the War Department of the United States, both as regards matter and form. It would seem in America that when a competent officer is selected to report, he is allowed a free hand as to scope, style, and length; his work is apparently not mutilated by superior intelligence at headquarters nor cut down by a stingy printing office."

"We are, of course, chiefly interested in Colonel Woodhall’s running criticisms, which give us a glimpse of ourselves as ‘others see us,’ and are invariably marked by a friendly frankness. His report suggests so many interesting points for comment that it is with reluctance we are compelled to notice only a few."

"On our army medical establishments generally he remarks that numbers, designation, rank, pay, retirement, etc., are not fixed by ‘law,’ by which we suppose he means statute, but by royal warrant, while the whole rests indirectly on an annual vote or appropriation for the army. This arises from the constitutional fiction that a standing army is a menace to civil liberty, and may be dispensed any year by a vote of the Commons; but although the rights of our soldiers seem to rest on such a shaky and ridiculous foundation, the balance is redressed by giving royal warrants the force of law, although seldom interpreted in a court of law."

"On voluntary retirement in the medical service, he states: ‘This voluntary renunciation of active service makes promotion relatively rapid, but at the same time the army loses many trained men in the prime of life, and the sentimental attachment to the service, which is a considerable element of efficiency, is liable to be weakened.’ But he apparently overlooks the very different conditions of our army, and especially medical service, largely in unhealthy foreign climates, from those of the United States; with us the privilege of voluntary retirement even in the prime of life is only the unavoidable alternative of wholesale sick leave and invaliding."

"On our ‘Morning Sick Report’ he remarks, probably in contradistinction to procedure in his own army, that it is not signed by any officer, and there seems to be no obstacle to any soldier who desires coming before the medical officer. That is so; our assumption is that the medical officer is the best, indeed the only competent judge as to whether a declaration of sickness be well founded or otherwise; but Colonel Woodhall does not seem to infer that our easy access to a medical officer encourages scheming; for he speaks from personal observation in our inspection rooms: ‘I was impressed with the rigor exercised in taking up men as sick. Soldiers that I should not have hesitated to excuse were summarily marked ‘medicine and duty,’ and so disposed of.’"

"Colonel Woodhall evidently considers our married roll absurdly large, for he declares it is ‘enormous, judged by any ordinary measure of a combatant force.’ Attendance on the families of soldiers not on the married roll being voluntary, and left to the good will of our medical officers, he remarks: ‘According to my observation, such voluntary attendance, although a very great tax on their (medical officers’ time and patience, is freely rendered and much appreciated.’ We heartily indorse this, all the more that the detractors of our medical officers never mention such voluntary and kindly labor, but represent that their time is engrossed with too purely military functions to the neglect of the professional."

"Our ‘stations’ correspond to the ‘post’ hospitals of the American army; yet another example of the invincible repugnance to the word station in that country, where it is always supplanted by some synonymous term."

"The temporary employment of hospital orderlies from the ranks is common with us, but, he mentions, is prohibited by ‘law’ (2 regulation) in the American army, which is probably judicious in view of the small fighting force of that army."

"The system of our hospital dietary is essentially different from the American; ours is based on individualism, with personal stoppages, theirs on collectivism, with the whole on a general debit and credit account. They have two classes of hospital diets, full and special. The former is supplied in bulk for twelve men daily, with a varied and liberal bill of fare for each day in the week; the special is, of course, ordered to individuals, and embraces a long catalogue of articles, among which ‘stewed oysters’ and ‘broiled ham’ will tickle the fancy of our medical officers."

"In view of our continuous service in all parts of the world, he thinks our medical history sheets useful documents; but they would be superfluous in America, as the information they afford is concentrated in a hospital register at Washington."

"Concerning recruiting, he somewhat erroneously states that attestation is ‘effectuated by a civil magistrate, not a military officer’; that was so up to ten years ago, but is now only true of out-stations. At all our great urban recruiting centers, and at the headquarters of regimental districts, approving field officers have the power of justices to swear in recruits; and in this way the old delays and obstructions in resorting to a civil magistrate are avoided. He observes that our ‘special enrollments are very frequent’; he may take them to be from fifteen to twenty-five per cent. of the whole, but we trust he is not imbued with the common fallacy that ‘special’ recruits are necessarily inferior; such enrollments arise in the great majority of cases simply from want of correlation, in growing lads, between
the hard and fast military standards of height and chest, which, after all, are only approximate, and in no way to be considered as ultimate physiological or vital facts. Nor, for all the outcry, do our 'specials,' under good food and training, long remain distinguishable as such in the ranks.

"As the Medical Staff Corps was to be particularly reported on, we have scanned this lengthy review of it with much interest. On the limitation of the standard of height, between sixty-three and sixty-five inches, he emphatically states, what we fully endorse and wish we could bring home to our opportunist military rulers, who seem to think any stunted creature good enough for a departmental corps: 'I am justified in saying that medical officers of experience do not regard with satisfaction the limitations of stature for these men; and it is obvious that for the conditions of our own service an undersized corps, with consequent inability to handle heavy men, would be unsuitable.'

"Our Medical Staff Corps, notwithstanding disadvantages, is evidently more highly organized than its American cousin, which, according to Colonel Woodhall, is most deficient in the intermediate grades of non-commissioned officers, and 'resembles a regiment made up of privates and sergeant-major.' He considers it 'one of the anomalies that, although on duty at all other stations and on troop-ships proceeding to India, the Medical Staff Corps does not serve in that empire.' But there are substantial reasons for the anomaly: a native hospital service had grown up in India long before the Medical Staff Corps was created, and the supersession of that native service by Europeans would not only be enormously expensive, but of doubtful utility, and, from the nature of the duties in an Indian climate, attended with the gravest risks.

"His comments on the Depot and Training School of the corps at Aldershot are of especial interest in view of the understandings we sometimes see made on it in the 'service' press. He says: 'All the Medical Staff Corps recruits at depot are diligently taught infantry drill. . . . Careful and constant observation of the drill, which was extremely interesting from the pains and thoroughness with which it was taught, showed that the medical officers at Aldershot had brought their battalion into an admirable and enviable military state. Necessarily adjusting the movements of their stretcher-bearers to those of their infantry, as we must to our own, I may say at once that I saw nothing except their zeal to recommend for our adoption; and in several particulars our own methods are simpler, the movements more quickly executed, and the exercises more diversified and better adapted to the general end in view—the speedy relief and collection of the disabled.'

"Again: 'The actual drill at Aldershot is admirably executed, but, in my opinion, our manual and drill as a whole are swifter, simpler, and better adapted to the purpose.' We would not, even if we could, now traverse these views, but rather present one more extract: 'I wish to emphasize the expression of my opinion that this instruction, like all I saw at Aldershot, was given with such intelligence and fidelity as to compel the interest and improvement of the men, and that in turn they acquired much of what was taught.'

"That is handsome testimony from an entirely competent foreign officer, whose mission was to criticise, not to praise. We hope it will not be lost upon those who on one pretext and another, and from the most apparent military jealousy, would, regardless of disastrous results, destroy, if they could, both the depot and the training it so well affords. For what are the objects of bearer company as of other military drill according to the report?

"The rigid adherence to the methods of the drill can not be commended too highly or imitated too closely. As in all other forms of military instruction, it is careful repetition and unvarying uniformity that lead to perfection and to automatic work when the test of battle comes.'

"On the question of medical service with the fighting line in the field, Colonel Woodhall remarks: 'The knowledge that a medical officer is with them (the fighting line) increases the morale of the command. In practice, unless fighting under general cover, I doubt whether it will be physically possible for any medical officer to reach many of the wounded where they fall, and an advancing line will very rapidly leave the medical staff in the rear unless that staff passes the disabled without assistance.' In other words, he clearly foresees that not only a highly trained but a very numerous medical service will be required to cope with the terrible demands of future battlefields.

"On our field equipment he writes: 'In my judgment our system of tenting in all its particulars, whether considered for shelter, artificial warmth, convenience of transportation, or general adaptability of camp, has nothing to acquire from that of Great Britain.'

"He strikingly points out that our 'whole scheme of hospital service in the field is based on the theory of invasion, and active columns proceeding from a marine base, where the general hospital is established, and whence the process of transfer to England of the seriously disabled is carried out.' Just so; as a power essentially maritime and insular, we must always consider our base a marine one.

"Colonel Woodhall witnessed our autumn manoeuvres of the First Army Corps, and expresses his supreme surprise that there was no field hospital service whatever trained with it. He says: 'Naturally, I did not inquire too curiously into the cause of the failure to utilize such an opportunity for practical work, but I believe the medical department was not responsible.' For all that, he is probably as well aware of the 'cause' as we are—namely, the penuriousness of the War Office and the entire indifference of the military authorities to medical training; but he utters a sentence of warning from which those responsible will not ultimately escape: 'Modern wars are too sudden in their onset to allow the medical department, which in the nature of the case has few current opportunities, to await for its mechanical training the pressure of immediate service.'

"Of Netley and Aldershot, in their combined functions, he writes: 'In some respects the courses at Netley and Aldershot overlap, and exertion is thus wasted. But taken as a whole, they both are admirable and are strongly recommended for our imitation.'

"'Could these institutions be more highly flattered?'

"Colonel Woodhall's last few pages relate to the physical training of our soldiers; his appreciation of our system may be gauged from the following sentence: 'Notwithstanding inferior material, there is no question that the British soldier looks better on duty, and as a soldier is more active than our own. To the systematic gymnastic instruction now in force, which is an amplification and an extension of the physical training proper, they are much indebted for this superiority.' Again: 'The physical development of the soldier, in whom the fighting instinct is naturally strong, gives to the British army much of the formidableness it possesses, notwithstanding certain deficiencies in the original material and other incidental conditions of the service.' From all of which it will be seen our American cousin is a just as well as a frank critic in army matters. We sincerely trust his criticisms on the withholding of medical training in field duties, which is absolutely culpable, will not be lost upon those who are primarily, as they will be held ultimately, responsible.'
Lectures and Addresses.

THE INAUGURAL ADDRESS
OF THE PRESIDENT
OF THE NEW YORK ACADEMY OF MEDICINE.
JOSEPH D. BRYANT, M.D.
Delivered before the Academy on Thursday Evening, January 17, 1895.

The foremost duty of one who is honored by his fellows—men is to express his grateful appreciation of the manifestation of confidence and esteem, and to pledge his earnest thought and conscientious labor to the support of the best interests of the charge intrusted by them to his guidance and care.

The fact that you have deemed it wise to honor me, and, too, out of proportion to my merit and expectation, by placing me at the helm in the affairs of the Academy of Medicine, is a tribute of regard and trust which, while it emphasizes the value of past conscientious effort, none the less admonishes one of the necessity of a continuous and unintermitting endeavor.

Indeed, I thank you sincerely for this earnest of your confidence, and beg to express the hope that no future official action of mine will cause the lodgment of a well-founded regret in the mind of any one.

The usages of the occasion that now claims our attention dictate that a careful consideration shall be given to the affairs of the organization to which we belong and to the advancement of whose prosperity and strength each of us should now pledge an unreserved and loyal support.

The attainment of this desideratum is made easy when earnest effort and honest self-denial and abnegation characterize the labor and attempts of men who are engaged in the exaltation and advancement of a common cause.

But it should not be forgotten at the outset that decided differences in honest opinions and in upright purposes are the inevitable products of earnest discussion, when engaged in by sincere and well-meaning persons, whether they are the prime factors of scientific bodies or of those of mighty nations. And, whichever they are, the results of deliberate conclusions, when secured by fair means, demand alike the sincere support of all who regard with proper thought the supreme importance of wise control, good order, and well-founded prosperity.

The endurance and thrift of every organization depend on the honesty, the harmony, and the productiveness of the administration of its affairs.

The Academy of Medicine is a definite and well-established organization in every sense of the term, and, like all similar ones, has assets of a material and, if you please, of immaterial nature as well, whose value and productiveness are amenable to the same influences as those of organizations of a baser nature.

The marketable value of the structural, landed, and monetary investments constitutes the common material foundation of this and other well-organized and enduring bodies of men; not only because each member of the organization exercises an inherent right in the control, but also because the members themselves can find culture, or comfort, or good fellowship in connection therewith whenever the inclination or opportunity to do so may arise.

Nor is this all in the instance of the Academy of Medicine, since within the structural possessions are stored the means of mental enrichment and professional exaltation which not only serve to stimulate and increase the fruitfulness of labor, but also begot opportunities and examples that attract to the field fresher energies, greater efforts, and increased prosperity, all of which are well exemplified by two significant words—increasing membership.

Unfortunate indeed it is when for any reason the worm of discontent or the canker of indifference fastens itself on the energy or loyalty of the members. Then, material assets of an organization—the landed, structural, and monetary; books, the means of mental enrichment; and membership, the basis of existence—all suffer from the dire effect of the unheeded influences of time, temper, and tempest.

The present condition of the common material belongings of the academy is well stated already in the usual reports bearing on these subjects. However, there are two other belongings, or assets, if you please, to which I desire to call your attention, because each should be cultivated with care and treated with circumspection and forethought in an equal degree.

I refer to the books—the library—and to the fellows—the members of the academy. The library should be regarded as a legacy from the present to the future of the academy, and from the present to the future of medical achievement, and indomitable energy should be wisely exercised in the various channels of activity to secure suitable amounts of money the income of which shall maintain the library at as high a state of efficiency as may be required to keep pace with medical attainment.

Fellows of the academy come and go, live, die, and are forgotten, except in the evanescent recollections of those who are near to them in the rank of departure. But good books—"the monuments of vanished minds"—are, as Milton said, "the precious life-blood of master spirits, embalmed and treasured up on purpose to a life beyond."

The larger and more comprehensive the library becomes, the greater and the more enduring will be the fame of the academy, and the more beneficent will be its influence on all things coming within the meridian of its activity.

There is not a member of the academy who can not with ease and without personal hardship garner an amount, no matter how modest, which will add the weight of its influence to the force necessary to maintain the library at a maximum state of efficiency. The yearly report shows the membership of the academy to be above seven hundred, and still exhibiting a healthy increase. Now, surely, if each of the seven hundred were to contribute an average of but one hundred dollars to the library fund, the income of the aggregate sum, added to other means now in our possession, would not only meet the wise demands of the
library, but also, in so doing, would enable the management to lessen much the yearly tax that is now imposed on the fellows of the academy.

While it is true, of course, that there are fellows for whom the contribution of a hundred dollars would constitute a genuine hardship, yet it is equally true that by far the greater number can each contribute twice or thrice that amount without the least well-founded inconvenience. It is a pure question of personal patriotism.

Those who are not blessed with sufficient funds to make contributions that are consonant with their sense of pride should not forget the facts that patriotic endeavor will bring prompt and cheerful aid from other than personal sources, and, too, that the "widow’s mite" is as expressive of earnest, honest intent as the munificent contributions of plenteous resources.

No matter what else may be done to meet this end, let each member constitute himself a committee of one for the purpose of adding his part to a fund that shall glorify his name, not in proportion to the amount given, but in proportion to the cheerfulness and ability of the giving.

All requests for aid and support should be made with becoming dignity and couched in terms that shall impress the fact that he who contributes to medical attainment gives to mercy’s cause.

While it is true that the library is the chief vital force of the academy, and that its healthful influence is essential for a proper growth of the organization, still, it is very necessary that the obligations of the academy to other demands be carefully considered as they arise. All financial exactions should be anticipated, provided for, and scrupulously met; moneyed obligations should not be incurred in advance of the ability of their suitable fulfillment; advice on sanitary public questions should be willingly though discreetly given. The desire to be as wise and thoughtful citizens as physicians should be welcomed and regarded as an earnest of increasing patriotism and conclusive of enduring national pre-eminence.

It should not be forgotten at this age and day that a reputation only for medical lore ill-rewards one for the heritage of a dwarfed sentiment or the palsied action bred of indifference or inattention to the common requirements of human obligation.

I can not at this time disregard the fact that, although we are members of a learned profession, and for this reason are believed to be in the enjoyment of established prosperity, there are some of our members who find it difficult to meet their annual obligations to the academy. For such as these I have the sincerest sympathy, and bespeak for them the indulgence and aid of the more fortunate members of the organization. Their burdens will be lessened in direct proportion to the magnitude of the contributions of those who are more favored and to the conduct of affairs with a suitable degree of economy.

A righteous consideration of the sense of duty and the rights of the taxpayers of the academy demand that no unnecessary or prodigal expenditure of the academy’s funds shall be permitted, that every avenue of unremunerative outlay shall be closed, and that all indulgences that constitute an unproductive drain on the treasury or a lessening of the dignity of the organization shall be promptly prohibited. So far as I myself am concerned, I am not in favor of any new departure or the maintenance of an old one that implies an unrequired drain on the treasury or the standing of the academy and its members.

The prospective products of the exercise of wise conceptions and well-directed mental endeavor constitute the immaterial expectancy of every scientific organization that adds facts to fancy, proof to conjecture, and excellence to mediocrity. If this is true, then it is easy to understand that for the achievement of success and the maintenance of good-fellowship both the material and immaterial factors of a body must be attuned in harmonious accord.

In this organization it should be recognized and admitted: at the outset that the chief aim of wise conceptions and of mental endeavor contemplates personal unity and improvement and the advancement of medical science; and that any ideas of policy or duty that harbor intentions prospective of doubt or dissension in any degree should be conceived with care, considered with deliberation, and enforced only after a patient heed has been given to the opinions and rights of all others who may be equally concerned.

I will not consume needless time in the recital of details, but, instead, will declare at once that I am well aware of the fact that increased honor is ever attended with increased labor and responsibility.

I shall regard it as my duty, and it certainly will be a pleasure, to labor untiringly in the support of every just and proper measure that emanates from within the organization. It will be my duty to place matters before you in such a manner as to enable you to act with proper understanding and without the danger of subsequent regret. It will be my duty also to hold the scales of deliberation in proper adjustment, in order that our business proceedings shall be characterized by the harmony, justice, and dignity that comport with our station in affairs.

Such, indeed, are but a few of the self-evident duties. Numberless others, many of which are yet in the future, and, perhaps, all unforeseen, will come unbidden and possibly unwelcome upon us. However this may be, it is to be hoped that we shall bear patiently all disappointments and distrust, and earnestly seek for the rewards of constancy, consistency, and courtesy. At all events, I wish it understood that I regard myself as a servant, and not as the master in your affairs.

May I not now bespeak your co-operation and support in all matters that are just and equitable? In all others than these I shall deserve your opposition.

It is to be regretted that the attendance at the academy meetings is not greater. A prompt and large attendance will beget a deeper and more lasting interest, foster a broader and more intelligent appreciation of the academy’s affairs, and correspondingly increase the esprit de corps of the members.

Finally, I desire that we bear with each other patiently at all times, being assured that all differences will be honest differences, and all conclusions both sincere and just.
Mr. President, in accepting from your hands the great trust which you have so zealously guarded, I comprehend very fully indeed the responsibilities that are incurred. Responsibilities which under ordinary circumstances one might accept with little fear are made doubly imposing now by the coming from a master hand.

Yet I am cheered by the thought that the results of the earnest effort and honest endeavor which you have exhibited may be duplicated by another, if he is wisely moved by the sense of duty and the power of earnest example.

Surely the task is made great by the knowledge that this organization has been fostered by the generous Purple, the genial Barker, the scholarly Jacobi, and the sagacious Loomis, and stimulated by the restless vigor of a Rooss.

If at the end of the term we can point to increased facilities, increased endowments, increased membership, and increased good-fellowship, then indeed shall I be gratified and feel that I have not lived in vain, and that I may exclaim, "Ye gave unto me this which I now return increased many fold."

Original Communications.

ENDOSCOPIC STUDIES
ON VEGETATIONS, POLypi, ANGEIOMA, MEMBRANous AND DIPHYThERIC URETHRITis, SUPpERATION FROM THE EjACULATORY Ducts, CYST OF THE COLlicULUS SEMINAlIS, ETC.

BY HERMANN G. KLOTZ, M.D.

Some of the cases reported on the following pages were briefly mentioned in a paper published in 1886, entitled Clinical Observations on Endoscopy of the Male Urethra (N. Y. Medical Journal, November 27, 1886). I then expressed the intention of describing them more fully in a separate paper. For various reasons, however, the notes remained untouched in my desk until two years ago, when my interest in the cases was renewed by the preparation of the article on Endoscopy for Morrow's System of Genito-urinary Diseases. Unfortunately, the space allotted to the subject did not allow of the introduction of clinical material. Some of the observations present such peculiar, almost unique, features that it seems justified even at a late date to place them on record. In several instances the importance of the endoscopic examination of the prostate urethra is particularly well illustrated, which by some recent authors seems to be considered unnecessary or impracticable.

The instruments and means employed for the endoscopic examination in all the cases were the same as I described and recommended to the profession in the paper mentioned above. The results obtained sufficiently testify to their usefulness, and explain why, in the face of their extreme simplicity, I have not been induced to give them up for more complicated although probably more perfect instruments.

I. Papillary ExcreScences: Vegetations.

Vegetations or papillary excreScences of the mucous membrane of the urethra, situated in or near the meatus, are of frequent occurrence, and, as they can easily be seen and reached, do not offer more difficulties to diagnosis and treatment than those commonly found in the sphenoid coro-narius glands, on and around the frenulum, known as venu-real warts or condylomata acuminatas. They share, however, with these their neighbors the tendency to obstinately return after having been removed by cauties or by mechanical means. Vegetations in the deeper portions of the urethra were first distinctly described by Vajda (Wiener med. Wochenschrift, 1882, p. 1029), not observed, however, during life, but on the autopsy table. Vajda cites similar observations reported by Morgagni, Hunter, Rokitansky, Dittel, Tarnowsky, and others.

The literature on the occurrence of multiple new growths of the male urethra has been collated by O. Rosenthal (Berliner klin. Wochenschrift, 1884, No. 23), who has published a minute description of a well-observed case; the polyp in this case probably were not of a distinctly papillomatous character. Since then Oberländer has described in his numerous publications a "urethritis papillomatosa," stating the occurrence of multiple papillary excrescences along the urethra; and more recently F. R. Eversole (St. Louis Polyclinic, vol. i, August 5, 1889) and F. M. Briggs (Boston Med. and Surg. Journal, October 24, 1889) have published cases of papillomatous growths, the latter particularly presenting features quite similar to those which I have observed in two instances.

Case I.—Arthur H., aged twenty-six years, a clerk, contracted gonorrhoea for the first time in the spring of 1888. The disease never showed any severe symptoms; the scanty discharge was usually removed by injections, but obstinately returned as a thin mucous fluid as soon as the syringe was laid aside. The patient therefore was subjected to endoscopic treatment from December, 1888, to March 9, 1889, applications of silver and iodine preparations being made about once a week. By the later date the mucous membrane of the bulbous urethra, which at first had presented a deep red color and finely granulated surface, had assumed an almost normal condition, while in the pendulous portion a number of dilated lacune Morgagni remained surrounded by patches of dark red, slightly infiltrated, and uneven mucous membrane. During this treatment small warts had developed on both lips of the meatus, which were removed with a strong solution of chromic acid. As a slight mucous discharge persisted in the morning, steel sounds from No. 28 to No. 30 F. were passed several times in March. Owing to a fresh exposure on March 23d, symptoms of acute gonorrhoea reappeared, accompanied by considerable swelling of the entire glans and pains in the lymphatic ganglia of both groins. By April 29th the acute symptoms had entirely disappeared, but warts had developed again on the lips of the meatus, in their posterior angle, and on the frenulum. As the short and tense condition of the latter seemed to favor the recurrence of the vegetations, it was immediately cut; the wound healed within a few days, but on May 7th the fossa navicularis was found to be filled with a thick yellow discharge of a peculiarly offensive odor; several small warts could be seen after cleaning. Endoscopic tube No. 24 F. was now introduced as far as the bulbous without any
difficulty, although not without considerable pain. After removal of the obturator the field of observation was occupied by a whitish mass of irregular surface which after cleaning and drying proved to be a cluster of papillomatous excrescences closely resembling common condylomata acuminata. On slowly removing the tube it became apparent that the entire pendulous urethra was studded with numerous smaller wartlike formations, which either singly or in groups or clusters ("nests" of Rosenthal) principally occupied the lower surface, some, however, growing from the upper aspect and from the lateral folds. They varied greatly in length, thickness, and shape, some reaching a length of about six millimetres; some were filiform and pointed, others club-shaped; some had a thin stem, while others were seated on a broader, substantial basis; some of the larger, cockcomb-shaped ones showed distinct branches and indentations. They did not bleed on being touched, and were set off by their whitish, glistening surface against the pink or red mucous membrane. The smallest excrescences seemed to be formed by a single enlarged papilla. Although no regular distribution could be observed, three larger clusters or tufts could easily be distinguished—one at the entrance to the bulb, one about in the center of the pendulous urethra, and one about two inches from the meatus—while nearer toward the orifice the warts became smaller and less numerous.

As the patient intended to go to Europe within a few weeks, it was desirable to remove the new growths as quickly as possible. In several settings the larger groups of warts were removed by means of the polyp guillotine (Morrow’s System, vol. i, p. 221); the smaller ones were cauterized with a concentrated (fifty-per-cent.) solution of chromic acid. On May 2d two single papillomata about three millimetres long at the entrance to the bulbus and a few small stumps nearer the orifice were all that could be found; they were removed with a ring-shaped curette. None of the procedures were accompanied by much bleeding, but generally followed for a few days by a moderate increase of discharge and pain during the micturition, May 23d. when the patient left for Europe, no warts could be seen. On his return in August a small group of warts was observed within about two inches and a half from the meatus, and October 21st a single growth on the same place; in both instances they were removed with the curette. On November 10th no excrescences of any kind were visible, although a number of dilated lacunae Morgagni indicated that the mucous membrane was not yet in a normal condition. A slight mucous discharge continued for some time, but up to February of the following year no recurrence of warts had taken place.

I have given the history of this case rather extenuately, because it shows that it required but a short time for the papillitary excrescences to grow to the extent they were found. Evidently before March 9th only a few small warts around the meatus had been present; on May 7th they were found in large numbers over the entire pendulous urethra; but it is more than probable that they did not begin to crop out until after the recurrence of more acute symptoms on March 23d, leaving not more than six weeks for their development.

It is difficult to account for the occurrence of papillomatous growths in the deeper portions of the urethra, particularly if they have to be considered, as several authors believe, as outgrowths of the normal papilla of the mucous membrane. According to Henle (Handbuch der systemat. Anatomie, ii, 2, p. 433), the mucous membrane of the male urethra is studded with papilla for a distance of from one to four centimetres from the mouth—that is, as far as the stratified pavement epithelium extends; they are particu-

larly numerous and close together near the meatus. Between the papillae and the smooth portions of the mucous membrane there lies a zone in which but single, slender papille are met with sometimes at long intervals. But in the above case they were found at a distance of at least twelve centimetres, or five inches, from the meatus.

In regard to the treatment, I can not agree with Rosenthal (loc. cit.) on the dangers from chromic acid. No bad effects will result as long as care is taken that none of the solution is allowed to flow upon healthy portions, but that it is confined to the papillary growths. This can easily be attained by using only very small cotton tampons or, better still, pointed wooden sticks, like tooth-picks, soaked with the acid. The treatment recommended by Oberländer—rubbing off the warts by means of cotton tampons—had not been heard of when this case was under observation, but I have more recently adopted it with good results in a case of vegetations in the portion of the urethra nearest the meatus. The best method, however, I have for several years found to be the galvano cautery, particularly where the excrescences were not too numerous.

In some cases, particularly in that of Briggs (loc. cit.), the papillomatous growths arrested the progress of Oliver-pointed bougies, and thus misled to the diagnosis of strictures of large caliber. Metal sounds of larger size do not meet with any resistance, although their passage may cause considerable pain and occasionally some bleeding. The discharge resulting from the vegetations is usually but slight and little colored.

Case II closely resembles the one just reported, and therefore will be treated more briefly. Mr. O., twenty-five years of age, came under my treatment in the fall of 1883, after suffering from chronic gonorrhoea for almost two years. Endoscopic treatment greatly improved the condition, but, owing to repeated and protracted absences from New York, could not be followed up with sufficient energy. On his return from a trip to Europe, where he had been treated by several authorities, in October, 1884, I found a group of condylomata acuminata obstructing the external orifice of the urethra; but, on examination as far back as the bulbus, no vegetations could be detected in the urethra itself, only a number of circumscribed granulations. On December 6th, however, the papillomatous growths had extended into the urethra and occupied the mucous membrane for about an inch and a half, either single or grouped, reaching almost the same size as in Case I. They were removed, partly with curved scissors, partly with the ring-shaped curette, within a few weeks, but in February, 1885, after a brief absence of the patient, had recurred to the depth of an inch without attaining the same size and number as before. After removal by similar means, including chromic acid, none reappeared, although, owing to the irregular attendance of the patient, the chronic gonorrhoea was not entirely cured until about January, 1887.

Case III is of special interest on account of the probable origin of the papillary growths. The patient, J. H., twenty-eight years of age, had come under my treatment in March, 1884, for epididymitis of the left side. He had been treated for stricture by a homeopath with "electrolysis" and sounds up to 28 F. for several months, but a slight discharge was still present. With the endoscope, on April 10th, about four centimetres from the meatus, several more or less elevated protuber-
ances were found, about the size of a split pen, with a broad base. Some of them had a granulated surface; others showed distinct, fine, elongated papilla; some blunt, some pointed. Opposite these warty growths, on the upper aspect of the urethra, there was a depressed scar in the shape of a glistening white stripe, about one centimetre long and three millimetres wide, overlapped by bulging portions of almost normal mucous membrane. Nearly the orifice another white scar, about one centimetre and a half long and even more depressed, was found. From the history it seems probable that the scars were produced by the “electrolytical,” or rather galvano-cautery, treatment, and that the warty excrescences were also due to the effects of the electric current, which did not exert equally strong influence on the lower surface as on the upper one. The papillomatous growths were removed by applications of caustics (sulphate of copper, carbolic acid, etc.), and proved quite obsolete, but finally disappeared definitely.

Case IV.—S., a porter, thirty-one years of age, had been treated for over a year with sounds and injections, but had still a slight gonorrheal discharge in July, 1882. At the entrance to the membranous portion a group of small excrescences not larger than a hsemoseed were discovered, which freely bled on touch; they had a broad basis and an uneven, warty surface. Another similar group was situated about half an inch farther back in the membranous portion itself, originating, as repeated observations demonstrated, from the right upper quadrant of the urethral circumference. Their location at a distance of about seven inches from the meatus, and at a spot where the endoscopic tube is particularly liable to irritate and to cause bleeding of any projecting portion of the mucous membrane, rendered the removal of these growths rather difficult. With a galvano cautery at my service, it would have been an easy matter to destroy them, but at that time I had to rely on caustics, chronic acid and nitrate of silver. In October, 1882, the last vestige had disappeared and none were observed afterward, the last examination having taken place as late as August, 1883.

Case V.—C. D., aged twenty-six years, for the last eight years had hardly ever been entirely free of urethral discharge, with frequent exacerbations of the condition. About an inch and a half from the meatus I discovered a cockscomb-shaped new growth, a third of an inch in length, growing from the lower wall with a rather slender, more stemlike base, with an irregular, distinctly warty surface. After removal with the guillotine it was found to consist of a number of soft warts. The stump was treated with the galvano-cautery and the wound healed rapidly. The urethral discharge, however, was much more obstinate.

Case VI.—G. St., aged twenty-two years, was under treatment in 1893 for incessant seminal emissions, having never had gonorrhea or any other venerous disease. To facilitate the introduction of large sounds metotomy was performed. Before the wound healed, warts began to develop within sight of the orifice, and within a short time spread to a depth of about two inches along the mucous membrane, densely covering the same on several places. In this case Oberländer’s method of rubbing off the new growths with two cotton tampons and application of dermolat proved efficacious, the warts being of tender structure, soft, and of recent origin.

II. POLYPI.

Quite different in some respects from the papillary excrescences, larger, single new growths are occasionally observed in the male urethra, which from their more or less smooth surface, their shape, and benign character, altogether from their resemblance to similar formations found in other cavities of the human body, may well be designated as polypi in the absence of a better, more strictly anatomical, or histological name. The favorite locality for the development of these real polypi seems to be the membranous portion, at least according to my own observation, which, I am aware, is at variance with that of other authors, who have found them in the pendulous urethra. As a rule they cause very few symptoms, except a continuous slight discharge; but, on examination with bongies a boule, or even with the urerometer, they will feign a stricture, and in reality have done so in several instances, while to steel sounds of large caliber they do not offer any resistance. The first case that came under my observation was reported in 1881 (Med. Record, August 6th). Several polypi were removed by means of an instrument devised for the purpose and called the polypi guillotine. They were situated in the membranous urethra. The largest one, after having been in strong alcohol for some time, measured six millimetres in length and four millimetres in width at its base. Since then several cases have been seen by me. The history of the patient on whom the largest one of these growths was found seems worth while to be given in detail, as it illustrates in an excellent manner the complicated condition which may exist in certain cases of “chronic gonorrhoea,” the difficulties and obstacles in the way of successful treatment, and the results which may be obtained by patient work without exposing the patient to the risk of sometimes unsuccessful operations, and without preventing him from attending to his business or profession.

Case VII.—F. K., aged thirty-one years, barber, first came under my observation in September, 1885, with a slight discharge, the remnant of a protracted gonorrhoea, lately complicated by symptoms of subacute cystitis. The urethral orifice was very narrow, surrounded by hard electrocautery, and therefore was dilated by cutting. The immediate result was satisfactory, but the patient neglected the after-treatment. He appeared again in December, 1886, with an exacerbation of the chronic discharge, which had not entirely disappeared. The meatus had partly contracted again; in the fossa navicularis a firm stricture was met with which hardly admitted a No. 14 French bougie à boule. After reduction of the secretion to a minimum, on January 15, 1887, a No. 12 French bougie passed the fossa navicularis with difficulty; at three inches and a half passed another stricture, but was stopped at five inches and a half. The electrocautery of the entire anterior urethra rendered it very difficult to establish a caliber of the urethra sufficient for the introduction of an endoscopic tube, and in spite of several incisions in the meatus, sounds, etc., it was not until April 15th that I succeeded in applying a tube No. 23, of three inches and a quarter in length, as far as the bulbous portion. The mucous membrane, almost in its entire length, presented a white, smooth appearance resembling scar tissue or that of a tendon, but formed a very uneven surface. Numerous prominences, particularly from the lower wall, bulged into the tube; some rounded, some conical, each one almost invariably bearing on the front aspect a distinct depression, the wide opening of a lacuna Morgagni. This, and the subsequent observation that applications to these lacune caused a gradual disappearance of the lumps, seemed to justify the opinion that the inflammation had principally started from the lacune, and that cell infiltration, formation of connective tissue, and subsequent cicatrization had taken place around the cavities of the lacune.
Morgagni. This view has found confirmation by the researches in pathological anatomy of E. Finger (Arch. f. Dermat., supplement 1 for 1891).

At the next examination, a few days later, a tube No. 23, five inches and a quarter long, was employed, but could not be passed beyond the bulb, where it met with obstruction, although sounds Nos. 24 and 25 had previously reached the bladder without difficulty. On removal of the obturator a peculiar view presented itself, which I have rendered as faithfully as possible in Fig. 19 of Plate I, vol. 1 of Morrow’s System. There protruded into the lumen of the tube a cylindrical body, slightly tapering toward the point; about three quarters of an inch long and an eighth of an inch wide at its base, of a dark pink color and a perfectly smooth surface. Further attempts to push on the tube proved fruitless, but revealed the origin of the tumor from the upper left quadrant of the field of view. The new growth was formed by very hard resistant tissue and was not very vascular. Unfortunately, my polypus guillotine was of too large a caliber to be introduced in this case, so I cut off at once a little more than two thirds of the growth with a sharp curett, cauterizing the stump with sulphate of copper, and removed some smaller pieces at subsequent sittings by curetting and by chronic-acid applications. On May 10th no trace of the tumor could be seen except a small white scar. Meanwhile the pendulous portion, particularly the mouth of the lacune, had been treated with solutions of silver and copper or iodoform at intervals of about four days. By the end of May the white protuberances had disappeared, and the openings of the lacune, which originally formed the center of the front aspects, had been greatly reduced in size and appeared on a level with the surrounding mucous membrane. When the patient had to leave New York soon after, he was able to introduce himself, without difficulty, a No. 24 sound.

Cases VIII and IX.—In two other cases I have observed new growths of much smaller size originating from the same locality—the entrance to the membranous urethra—single in the case of Mr. H., aged thirty-two years, where the diagnosis had been made already with the greatest probability by Dr. F. Eversole, of St. Louis, who sent the patient to me on his removal here; double in that of Mr. P., aged thirty-five years. In both instances a whitish, sharply pointed, wormlike body, not more than a quarter of an inch in length, would be seen to be lifted from the level of the mucous membrane by the edge of the tube and to enter into its lumen. Like the larger cylindrical polypus in Case VII, they were quite firm and tough, with a smooth surface and no tendency to bleed. They could be removed only with great difficulty by means of the curette.

These small growths did not cause any objective symptoms, neither obstruction nor discharge, but they seemed to be the cause of a certain irritation of the entire urethra, which became manifest by a burning pain in the deep urethra and frequent desire to urinate. After removal the new growths did not show a tendency to return. The disagreeable sensations in the urethra ceased after removal. In both instances I have been able to ascertain the permanency of the relief obtained by the patients.

III. Angioma Cavernosum.

Case X.—In 1884 I had occasion to examine the urethra of a young lawyer who had been repeatedly treated for gonorrhoea, the last attack lasting then about two months. An endoscopic tube, No. 25 F., about three inches long, the largest caliber the meatus would admit, was introduced into the bulb. On its withdrawal, when the middle of the pendulous portion was reached, suddenly the left side of the urethral wall bulged into view. The protruding portion of the mucous membrane was found to be of a smooth surface and a dark bluish color, of the shape and size of a coffee bean, sharply defined at the base from the dark pink surrounding portions. The tumor was soft and easily yielded to the pressure of the tube, although on introduction it seemed to offer a slight resistance. On close inspection within the tumor a number of separate cords, separated by yellowish wide lines resembling the rings of a coil, could be distinguished, apparently representing dilated bloodvessels, and imparting to the whole mass the character of a cavernous angioma.

It is difficult to decide exactly whether this was really a cavernous tumor, or whether a pre-existing or accidentally formed gap or a localized thinning out or weakening of the tunica albuginea of the corpus cavernosum allowed the cavernous tissue itself to protrude and to form a kind of diverticule. I am inclined to accept the former opinion, principally on account of the eminently sharp angle which the base of the protuberance formed with the adjoining portion. I have seen similar conditions in small cavernous tumors of the mucous membrane of the hard palate and the anterior aspect of the soft palate, when the tumor would appear with a very distinct contour whenever the muscles of the palate were contracted.

The occurrence of such cavernous swellings is not without practical bearings, because any injury done to them may cause serious hemorrhage. The swelling in this case was sufficiently palpable to produce the sensation of narrowing of the urethral lumen on examination with a bougie à boule or even with a uritrometer. Mistaken for a stricture, it might be made the object of internal urethrotomy and thereby cause hemorrhage, thrombosis, etc.

IV. Croupous or Membranous Urethritis and Diphtheria of Urethra.

The number of published cases of true membranous urethritis is a limited one. Tarnowsky mentions cases reported by Pitha and others. A. Pajor (Arch. f. Dermatol., xxi, p. 3) describes several cases and reviews those observed by others. It appears from the perusal of this paper that conditions widely differing among themselves have been included under this name, from a small whitish patch to the shedding of almost the entire lining of the urethra in the shape of a membranous tube. The following case, while not so far developed, undoubtedly deserves to be considered one of membranous exudation upon the surface of the mucous membrane.

Case XI.—Sch., aged thirty-one years, a musician, who had been under my treatment before for gonorrhoea and herpes preputialis, called at my office October 5, 1884. One week ago, about eight days after sexual intercourse, eight months after the disappearance of the last attack of gonorrhoea, he noticed a slight discharge from the urethra, for which he applied injections of "maitico," which he had used before with good results. This time they were followed by pains in the anterior urethra and very slow, dripping evacuation of the urine. In my presence he could void the urine only in a very thin stream in spite of considerable efforts; the urine itself was almost clear. An elastic bougie No. 15 was arrested at two inches, a steel sound, No. 16 F., passed into the bladder; a slight hemorrhage followed, apparently originating from the site of
the resistance. Salicylate of sodium with extract of belladonna was prescribed and all local remedies set aside.

October 7th.—The patient reported that on the preceding afternoon a wormlike substance of a light color had been passed with the urine. A moderate quantity of purulent discharge was noticeable; the urine came in a very thin stream and was cloudy. Endoscope No. 23 was now introduced as far as the bulbus. On inspection the lumen of the tube was found to be filled up by a yellowish-green, gelatinous substance which was easily removed with a blunt hook. It proved to be a string about an inch and a half long and a fourth of an inch thick, and was apparently a solid mass; I searched in vain for a lumen, as it greatly resembled the casts seen in ecuprous bronchitis. A few smaller membranous pieces of white color were removed. The mucous membrane presented a moderately dark-red, smooth surface in the posterior urethra; in the central portion, where it bled considerably, the surface was eroded in several places with fine red points. The affected portions were dusted with iodoform and an injection of linewater diluted with two parts of water was ordered to be made four times a day.

October 10th.—The sensitiveness of the urethra was greatly reduced, the urine was emptied with but slight difficulty, the purulent discharge, however, had increased, the urine being cloudy. Endoscope No. 24 could not be introduced, but No. 23 reached the bulbus, although with difficulty and under considerable pain. It revealed the mucous membrane covered over a large area, extending almost from the meatus to the bulbus, with a white, thin skin resembling that of boiled bronchitis. After its removal the surface was partly smooth and pale pink, partly of a decidely scarlet color, moist, with a rough, worm-eaten-like appearance, but did not bleed. These spots were touched with a ten-per-cent solution of nitrate of silver, the injection changed to zinc sulphocarbulate, a grain to the ounce.

October 14th.—The patient reported the discharge of a number of pieces of a white, membranous substance and on one occasion of some blood with the urine, but little pain, less urgent desire to urinate, and diminished secretion. Endoscope No. 23 showed the formation of membranes over a very limited area only; some portions were covered with a thin white film, after the removal of which they appeared eroded, moist, dark red, and rather sensitive. The other parts had assumed a more natural pink color and smooth surface. Diluted liquor ferri perchloridi was applied and an injection containing one part of the same drug in two hundred of water was substituted.

October 17th.—Little pain, but slight haemorrhage, or rather dripping of a bloody urine or secretion from the urethra. Patient can retain urine two hours and a half in the daytime; has to get up at night but once or twice; urinates in a much fuller stream; urine slightly cloudy but acid; contains some small pieces of membrane.

October 20th.—Reports the evacuation on the 18th of several blood coagula with the urine; after an injection, difficulty with the urine and temporary inability to empty the bladder, until the spontaneous ejection of a fibrinous clot brought relief. A small quantity of purulent discharge can be squeezed from the urethra. Endoscope No. 23 shows a number of small patches which are very sensitive to the touch, slightly eroded, bleeding from several distinct fine points. Nearer the meatus some portions are dark red but smooth. The entire length of the urethra was dusted with powder of iodoform; injection of nitrate of bismuth and pills of cephalin and eubels internally.

October 22d.—Hardly any pain, but copious purulent discharge; with endoscope No. 23, less tendency to bleed; application of iodoform.

October 26th.—Continuous flow of pus; slight pain near meatus; urine less cloudy. Irrigation with solution of corrosive sublimate (1 to 15,000) followed by slight oozing of blood; continued pills.

November 1st.—Discharge became much less after two days; urine clear, followed by a few drops of blood at the end; slight pain in one spot in the anterior urethra. From this date on all the symptoms gradually disappeared under the injection of the liquor ferri perchloridi solution.

The following two cases do not strictly belong here, as the endoscope played no important part in their observation. I have no doubt that the affection of the urethra in both was a diphtheritic one, although I am unable to bring forth any positive proof. The rarity of diphtheritic lesions of the urethra (see F. J. Brown, Journal of Cutaneous Diseases, vol. viii, p. 289, 1890) will justify, I believe, their publication here:

Case XII.—Mr. St., who had been under my treatment for chronic gonorrhoea up to May, 1869, on October 21st of the same year returned from a business trip with a fresh affection of the urethra. About eight days ago, three or four days after sexual intercourse, he noticed a slight pain in the orifice, with very scanty discharge. The flow rapidly increased within a few days in spite of the use of a mild injection, but remained more watery. When I saw the patient on the above date the entire glans penis and the prepuce were considerably swollen and reddened; the mucous membrane of both lips of the meatus showed a number of irregularly shaped, pale-yellow spots. Owing to the tense swelling of the glans it was impossible to distinctly decide whether these spots were due to a superficial loss of substance or to an exudation on the surface. The general condition of the patient was by no means satisfactory; the inguinal glands were somewhat enlarged and sensitive on both sides. Irrigation with a mild solution of corrosive sublimate (about 1 to 40,000) and permanganate of potassium was very painful. Iodoform was applied to the yellow spots, and an injection of acetate of lead and boric acid was prescribed.

October 23d.—The swelling of prepuce and glans had greatly subsided; the meatus was still very red; the mucous membrane of both lips showed circumscribed areas of a yellowish color, which gave the distinct impression of membranes formed upon the surface or within the superficial layers of the mucous membrane itself; they certainly were not ulcers. A very copious watery discharge had continued; the urine was somewhat cloudy; moderate pain in the region of the kidneys. Irrigation with corrosive sublimate (1 to 46,000); salicylate of sodium internally.

25th.—Swelling almost entirely disappeared, except around the urethral orifice itself, which was still quite hard to the touch. The membranous coating was much less extended, and on October 27th no trace of it was left, while a watery secretion continued, and the swelling of the left inguinal glands was noticeable for some time. The healing process was altogether very slow, and when the discharge finally stopped, or was reduced to a minimum, the anterior portion of the urethra was found to be narrowed down to admit a No. 21 F. sound with difficulty.

Case XIII.—Mr. K. had been under my treatment since February, 1898, for syphilis, which heretofore had been of a very mild type.

November 7th.—He reported that for some time he had noticed a slight discharge from the urethra, and had used with good results an injection of chloride of zinc (five grains to four ounces). Within the last two days, however, he had experienced quite severe pain in the urethra, with frequent desire to urinate, sometimes without being able to accomplish this on
account of a severe pain which was felt as soon as the outflowing urine reached a certain spot. The meatus and the entire glans were of a deep red color and intensely swollen; the inside of the lips was coated with whitish-gray membranes, resembling felt. The urethra, for about three inches, could be felt as a hard, thickened cord; there was a thin, watery discharge of a dirty-gray color, containing small, greyish crumbled particles of tissue in suspension. The patient was feverish, with loss of appetite and great general depression. An attempt to introduce a Nélaton catheter, No. 8 F., failed on account of the severe pain, but was followed by spontaneous evacuation of the urine. Applications of lead-water with boric acid brought but little relief until after the expulsion on the next morning of a membranous substance, which was found upon the cotton placed around the meatus.

9th.—The swelling and hardness of the parts had largely subsided, only the lips of the meatus were still swollen and sensitive; near the orifice remnants of the membranous infiltration were found; the other portions looked red and moist, suggesting loss of the epithelial cover.

After November 11th the symptoms rapidly disappeared, only the orifice continued for a longer period to present a very tender, somewhat eroded surface, and, like the rest of the urethra, to be extremely sensitive. This tenderness proved a serious obstacle to the final cure of the at no time copious or purulent discharge. The general health of the patient, which at the time did not seem to be influenced at all by the syphilitic infection, gradually improved. During all this time, and for several months afterward, no symptoms of syphilis whatever were apparent, although all specific treatment had been suspended.

V. PURULENT DISCHARGE FROM THE DUCTUS EJACULATORIUS; CYST OF THE UTRICULUS (1).

It has been but rarely described as observed in endoscopic practice that purulent discharge was found oozing from a distinct spot. In the paper mentioned above I referred to a case in which a small drop of a white, milky fluid was seen to ooze from a minute spot on the upper surface of the urethral lining, about an inch forward of the membranous portion. This was exactly observed on the very same spot on different examinations at different times. From the location I concluded that the opening from which the fluid emerged was the mouth of the duct of one of Cowper's glands. In the following case the source of a purulent discharge was apparently the ductus ejaculatorius:

CASE XIV. — A. S., twenty-one years of age, a barber, came under my observation in August, 1886. As his father informed me, he had been sent to work in a factory when quite young, and had quickly acquired the habit of self abuse. About a year ago he had contracted gonorrhoea, which after a rather acute course of several weeks had left a moderate discharge, sufficient to form a thick yellow drop on a rag which was wrapped about the orifice. The meatus showed extreme redness of the mucous membrane and several folds and deep furrows, while the lower portion was covered by a thin membrane. This was cut through immediately, as it barred the use of any larger instrument. Not until November 18th, after several relapses of copious secretion, cystitis, etc., was I able to make an examination with the endoscope. No. 23, later 24, reached the prostatic portion without difficulty. The mucous membrane of the entire posterior urethra was dark red and finely granulated, particularly on both sides of the caput gallyinginis, extending into the furrows on both sides of the collienis seminalis itself. The anterior portion of the urethra showed but slight lesions near the meatus. On subsequent examinations I found these furrows covered with pus or pus flakes, and could distinctly watch a small drop of pus oozing out of a minute opening; after wiping it off, on pressure with the edge of the tube a new drop could repeatedly be squeezed out. This could be observed on several subsequent examinations; at first the discharge appeared on both sides, but after December 18th only on the left side of the patient could the purulent drop be squeezed out with the edge of the tube. Applications of solutions of nitrate of silver (two, five, and ten per cent.) and of iodoform and iodoform-ether seemed to reduce the suppuration and at times to suppress it entirely, but it returned over and over again as soon as the patient had an emission. I then tried to enter the opening with probes and with a long cannula of a Pravaz's syringe constructed for the purpose, and after several futile attempts succeeded in entering the point of the syringe and in injecting a few drops of a two-and-a-half-per-cent. solution of nitrate of silver. The result was apparently a very good one; after every application the quantity of the purulent discharge became smaller. On February 1st the syringe was not used, but only an application of a ten-per-cent. solution of silver and iodoform to the site of the oozing point was made, and February 3d symptoms of a very acute epididymitis of the left side set in and rapidly developed into a severe and painful swelling. The inflammation at one time threatened to extend to the right epididymis, but fortunately the progress was checked.

February 22d.—The epididymitis had passed off sufficiently to allow of endoscopic examination again, when the prostatic urethra appeared in an almost normal pink color, with a perfectly smooth surface; no pus could be squeezed out on the locality of its former appearance either then or on subsequent occasions up to May 24, 1887.

I have had the patient under occasional observation ever since, and have treated him repeatedly for fresh attacks of gonorrhoea, but never have I been able to notice similar conditions again.

The same good final result was not obtained in another observation with similar features.

CASE XV. — W. K., aged about twenty years, a student, came under my treatment about seven months after his first infection with gonorrhoea. The disease had never entirely ceased, but had broken out with renewed copious flow of pus on several provocations. The case proved a very obstinate one, and not until after four months had the acute symptoms sufficiently subsided to allow of an examination with the endoscope. This revealed an accumulation of pus in the membranous portion, and at subsequent sittings I could observe that on approaching the prostatic portion, the tube would suddenly be filled with a more or less watery, but slightly sticky, generally opaque or slightly blood-tinged fluid. Applications of different drugs, among them the peroxide of hydrogen, gradually changed the character of the fluid to an almost clear condition; it became less in quantity and at times disappeared altogether. The discharge from the urethra had stopped and the filaments in the urine become very insignificant, when suddenly, without any apparent cause, the left epididymis showed great tenderness and became the seat of a comparatively mild inflammation. When the patient had to leave New York soon afterward, the epididymitis was entirely cured, no discharge could be seen, and the urine was perfectly clear and almost free of threads; but I was informed that a slight discharge had returned afterward. The elusion of a more or less clear, watery fluid into the cavity of the endoscopic tube on its entering the prostatic urethra I have observed in several cases where there existed neither a dis-
charge nor even a history of gonorrhœa, but where the patients complained of a constant annoying, not clearly describable, sensation at the site of the prostatic urethra.

Case XVI.—In one instance I have seen the colliculus seminalis forming a pea-sized protuberance of a bluish-white color, almost transparent, making the impression of a cyst filled with serum. On pressure with the edge of the tube, a considerable quantity of a clear, watery fluid was emptied into the urethra. A slight depression on the surface tended to indurate the sinus prostaticus or the orifice of the uriculus. The galvano-cautery was applied to the most prominent part of the swelling. Since then I have not observed again the copious discharge of watery fluid. At the next examination the colliculus appeared but slightly enlarged, with a uricular orifice of the form and size observed in healthy persons. I have little doubt that in this case there existed a cystic dilatation of the uriculus, probably with the product of its own glands. Belfield (Jour. of the Amer. Med. Association, April 21, 1894) has recently called attention to the importance of this generally neglected organ. In the face of the great difficulties of examining this portion of the urethra, I feel somewhat reluctant to make the diagnosis of a cyst more positively. The application of the galvano-cautery was followed by great alleviation of the patient’s complaints.

VI. Examples of the More Frequent and Usual Conditions in Chronic Urethral Disease.

The observations reported in the foregoing represent almost all the unusual and particularly interesting cases out of a large number of patients subject to endoscopic examination and treatment within almost fifteen years. In the largest number of instances only less striking and less remarkable conditions were found. If I am not entirely mistaken, much of the disappointment experienced by those who have endeavored to apply the endoscope for diagnosis and treatment of urethral diseases has been due to the exaggerated expectations of meeting with such extraordinary conditions, instead of other trivial and apparently less important lesions, which seemed hardly worth the trouble of endoscopic examination. Still, I believe we have to share this experience with other specialists, particularly with the otologist, the laryngologist, and others. The bulk of their cases will show only conditions due to chronic catarrhal inflammation, and a small percentage only will represent cases of tumors of all kinds and other more or less rare phenomena. These simple conditions, however, furnish a fruitful field for therapeutic action, and fully justify the increased outlay of work and time spent on the examination with special instruments and local treatment rendered possible by these means. It therefore occurred to me that it would not be without interest to add a few examples of such cases as are likely to occur most frequently in practice, and apt to illustrate the combination of various pathological conditions in actual practice. Most of these cases had been prepared for my article on Endoscopy in Morrow’s System, but want of space prevented their insertion:

Case XVII.—K, twenty-seven years of age, has had gonorrhœa at different times. For the last eighteen months, in spite of continued treatment with injections, sounds, etc., he has never been entirely free of urethral discharge, which on the slightest provocation became quite copious again; has had cystitis and very obstinate rheumatism. Urine slightly cloudy,

with numerous filaments. Endoscope No. 26 easily reaches the bulbous, where the mucous membrane appears moist, dark red, of a tender, somewhat infiltrated texture, easily bleeding. Central portion of pendulous urethra almost normal; in the anterior region a number of dilated, dark-red, and moist lacunæ Morgagni; congestion diminishing toward the meatus.

Case XVIII.—M., aged thirty years, has had gonorrhœa for the last two years, at no time of a very severe character, but constantly undergoing exacerbation on drinking, etc. Meatus very tight. After meotomy endoscope No. 26 shows anterior portion of prostatic and the membranous urethra in a state of congestion; posterior portion of pendulous urethra normal. In the anterior half a number of prominent lacunæ and dark-red rough patches in the lateral folds.

Case XIX.—B, aged twenty-four years, got gonorrhœa in January with epididymitis on both sides; in April, after treatment with deep injections, a small white drop remained in the morning. Endoscope No. 24 shows but slight redness in posterior parts; in the pendulous portion a number of wide and dark-red lacunæ and longitudinal furrows with dark, uneven, worn eaten-like surface.

Case XX.—A., aged twenty-six years, had gonorrhœa six years ago, which lasted a year; eight months ago, for the second time gonorrhœal infection. A discharge continues in the morning with a number of filaments in the urine. With endoscope No. 21 the membranous portion appears red and edematous, bleeding at its entrance; pendulous urethra normal for almost two thirds of its length; the anterior third rigid, uneven, dull red, lusterless surface; symptoms decreasing toward the meatus.

Case XXI.—B., aged thirty years, has had gonorrhœa frequently within the last fifteen years; a year ago had two strictures cut; a thin, viscid, whitish secretion continues, with numerous thin threads. Endoscope No. 28 shows normal condition of prostatic and distal half of membranous portion; anterior half of membranous and bulbous urethra dark red, granulated, bleeding; in pendulous portion scars along the upper wall surrounded by dark-red, moist, bulging folds; lacunæ moderately wide and rough.

Case XXII.—H., aged twenty-eight years, had gonorrhœa several times; lately epididymitis. In spite of treatment with sounds, deep injections, etc., some discharge persists. Endoscope No. 24 passes with difficulty through anterior portion, easily through deeper parts. Membranous and posterior half of cavernous urethra smooth and pale pink; central and anterior third of the latter rather resistant, with a number of small longitudinal fissures; central figure irregular, triangular in some places, surface rough, granulated, dark red, of a dull, dirty shade; in some places white, firm, almost cicatricial condition.

Case XXIII.—G., aged twenty-three years, brewer, has had gonorrhœa several times. Seven years ago transient retentio urinæ, which has occurred frequently within the last year; no discharge for some time, but frequent pain in perineum. Per rectum, prostate gland distinctly enlarged; pressure produces a grayish, thin discharge from urethra. Endoscope No. 24 enters membranous portion with a sudden jerk; shows colliculi seminalli considerably swollen, dark red, with uneven surface, easily bleeding; membranous portion white cicatricial tissue; pendula normal, except for a number of wide lacunæ and moderate diffuse redness in the anterior portion.

Case XXIV.—KL, aged twenty-six years, has had gonorrhœa several times; the last time four months ago, but now no discharge for several weeks; complaints of severe burning during and after micturition; urine perfectly clear; no threads. Endoscope No. 25 easily reaches the bulbus; shows diffuse redness and uneven surface in posterior portion of pendula; central
and anterior portions normal except a number of dark-red, almost brown, dry, slightly corroded patches in both lateral folds, which stain dark brown on being touched with tincture of iodine.

42 East Twenty-second Street.

HYPNOTISM
IN ITS RELATIONS TO CRIMINAL JURISPRUDENCE.

BY THOMAS JAY HUDSON,
WASHINTON, D. C.
ATTORNEY AT LAW; AUTHOR OF "THE LAW OF PSYCHIC PHENOMENA"; "HYPNOTISM A UNIVERSAL ANESTHETIC IN SURGERY," ETC.

I have been asked to pass a scientific opinion on the question whether hypnotism can be successfully employed to induce the commission of crime, and a legal opinion concerning the status of hypnotism in criminal jurisprudence. There are perhaps no two questions of more vital interest or imminent importance than these. When a confessed murderer is acquitted on the plea that he was hypnotized and compelled to commit the crime, a question is presented which is in some respects cognate to the old problem of emotional insanity. It is, however, of infinitely greater importance than the latter, for the obvious reason that emotional insanity could be made available as a defense only when it could be clearly shown that the victim had so grossly invaded the private rights of the accused as to deserve his punishment, whereas the defense which consists wholly of the allegation that some third person compelled the commission of the crime by means of hypnotism is equally open to the averger of a grievous wrong and the coldest-blooded murderer that ever scuttled a ship or cut a throat. It is obvious that if such a defense is once admitted as an element of criminal jurisprudence, a very wide and a hitherto unexplored avenue of escape is opened to the criminal classes. Nevertheless, when a criminal is acquitted on such grounds it may be said in extenuation that the jury entertained a "reasonable doubt," or invoked the old common-law maxim that "it were better that ninety-nine guilty men should escape than that one innocent man should be put to death." But when a confessed murderer is not only acquitted of the crime, but the alleged hypnotist is convicted of murder in the first degree on the testimony alone of said murderer, the question assumes a far more serious aspect. If such a thing can happen no man is safe who incurs the enmity of one of the criminal classes. As the books say of the charge of rape, "it is an accusation easy to make, but difficult to disprove." In the present state of popular opinion on the subject of hypnotism it is a charge impossible of refutation. The popular belief on the subject may be summed up in two sentences:

1. It is the popular belief that a person may be hypnotized at a distance and against his will.
2. It is also believed that in the hypnotic state a person is under the absolute dominion of the will of the hypnotist, and can be compelled to perform any act, however repugnant to his feelings or conscience.

Obviously, if these two propositions are true, hypnotism has a legitimate place in criminal jurisprudence. The scientists, however, who hold that hypnotism can be employed for criminal purposes do not all agree as to the truth of the first proposition, but they sustain the second with practical unanimity. It is to this second proposition, therefore, that we must first direct our attention, for if that is found to be untrue it is unimportant whether the first is true or false.

It must be premised that the science of hypnotism is yet in its infancy. No man can safely predict its future, as to either its uses or its abuses. That it is useful when legitimately employed no one who is acquainted with the facts will deny. That it may be employed to the detriment of its votaries is a proposition that is equally true of everything in Nature. That when its laws are understood they will be found to be promotive of the highest good of the human race is a proposition sanctioned by every discovery yet made in the domain of Nature's laws.

Little is known of the ultimate possibilities of hypnotism, there are some things about it that have been definitely ascertained and are, broadly speaking, as well known now as they can ever be known. It is not necessary for one to be able to calculate the eclipses to enable him to know that the earth is round or to grasp the fundamental hypothesis of gravitation. Nor is it necessary for us to know the future possibilities of hypnotism to enable us to grasp its fundamental laws, since they have been definitely formulated.

Broadly speaking, we know what hypnotism is, and we know at least one of its fundamental laws. The researches of the European scientists have definitely settled that much, and for the purposes of our present inquiry it is sufficient.

The word "hypnotism" is derived from the Greek ὑπνώσις signifying "sleep." Dr. Braid, who was the originator of the term, defined it as "nervous sleep," or induced sleep.* This implied the theory, then prevalent, that a subject must be asleep in order to exhibit the phenomena of hypnotism. Professor Lièbault, of Nancy, extended the researches of Braid, and immortalized his own name by the discovery of the law of "suggestion." Professor Bernheim, a pupil of Lièbault's, in conjunction with the latter, discovered that the Braidian definition was too limited in its scope to embrace all the phenomena, inasmuch as it was found that many of the distinctive results could be produced while the subject was in what Bernheim terms the "waking condition." Bernheim, therefore, defines hypnotism as "the induction of a peculiar psychic condition, which increases the susceptibility to suggestion."† This implies the theory that persons are normally susceptible to "suggestion." This conclusion, however, does not seem to be warranted, except in the sense that all are subject to the influence of others. There must be some abeyance of the objective faculties in order to produce the phenomena of suggestibility in the hypnotic sense—that is, in the sense that a suggestion can produce an hallucination. My definition of hypnotism would, therefore, substitute the word induces for "increases" in Bernheim's definition.

* Neurypnology, p. 13.
† Suggestive Therapeutics, p. 15.
As before remarked, Professor Liébault discovered and formulated the law of suggestion. That law is now almost universally recognized by scientists throughout the civilized world as the potent factor in hypnotism. I say "almost," for there are still a few exceptions, consisting of a constantly diminishing number of the followers of the late Professor Charcot, who believed that hypnosis could be induced only in hysterical patients. There is one other French "scientist" who succeeds in astonishing himself and amusing the scientific world by the production of phenomena which demonstrate nothing but his own ignorance of the principle of suggestion. Then there is one English author who recently produced a universal guffaw in the scientific world by publishing an expose of the Frenchman, and succeeded in astonishing all Europe and America by demonstrating the fact that he knew less about the subject than the Frenchman himself. With these unimportant exceptions the law of suggestion is universally recognized among scientists.

Formally stated, the law is this:

Persons in an hypnotic state are constantly amenable to control by suggestion.

BROADLY SPEAKING, SUGGESTION, AS THE TERM IS EMPLOYED IN HYPNOTIC SCIENCE, IS A STATEMENT (TRUE OR FALSE) MADE TO AN HYPNOTIC SUBJECT. ITS POTENCY RESIDES IN THE FACT THAT THE HYPNOTIZED SUBJECT UNHESITATINGLY ACCEPTS THE STATEMENT OR SUGGESTION AS TRUE, AND ACTS ACCORDINGLY. THUS, AN HYPNOTIC SUBJECT MAY BE MADE TO BELIEVE THAT HE IS ANOTHER PERSON, OR THAT HE IS AN ANIMAL, OR A DEMON, OR AN ANGEL, AND HE WILL ASSUME THE CHARACTER AND ACT THE PART TO THE LIFE, WITHIN THE LIMITS OF HIS PHYSICAL OR MENTAL CAPACITY. HE MAY BE MADE TO GET DRUNK ON WATER BY SUGGESTING TO HIM THAT IT IS BRANDY; AND HE MAY THEN BE MADE SOBER BY GIVING HIM BRANDY ACCOMPANIED BY THE SUGGESTION THAT IT IS AN ANTIDOTE TO THE PREVIOUS "STIMULANT."

These are the fundamental facts of hypnotism as they are recognized by the public. And it is upon these facts, thus broadly stated and superficially understood, that the conclusion has been based that hypnotism can be employed as an agent of the criminal. It is, perhaps, a natural conclusion for one who has witnessed only the common platform experiments. He sees the subject thrown into a state that is to him mysterious and inexplicable. He sees the subject in that condition become apparently under the absolute control of the operator and dominated by the most absurd suggestions. His natural conclusion is that, if the operator chose to suggest to the subject that it was necessary for him to perpetrate a crime, he would be compelled to do so in obedience to the law of suggestion. This is the first conclusion at which the European scientists arrived. But they were not content with mere platform experiments and abstract deductions. They had instituted a series of laboratory experiments in which criminal suggestions constituted the salient feature. Subjects were hypnotized and paper daggars were placed in their hands, and the suggestion was made that it was extremely desirable that some imaginary person, or real one for that matter, should be incontinently slaughtered. It is needless to say that the suggestion was in every instance obeyed with the greatest alacrity. It is almost superfluous to add that the experimenters, who were mostly medical gentlemen, were practically unanimous in the opinion that hypnotism was a very dangerous force in the hands of anybody but doctors.

It is my purpose in this paper to show that this view of the case is to the last degree superficial, and evidence a singular lack of appreciation of the real scope and significance of the law of suggestion. In their view of the question, suggestion would be confined to the oral declaration of the hypnotist to his subject. The truth is that the suggestions of the hypnotist constitute the least important part of the suggestions that dominate the mind of the subject.

Suggestions are divided into two classes—namely: 1. Suggestions by a second person, as by a hypnotist. 2. Auto-suggestions.

The first class is again subdivided into two classes—viz.: 1. Oral suggestions. 2. Mental suggestions. With the latter class we shall have nothing to do, as it belongs to a higher phase of psychic phenomena than we are considering.

Auto suggestions are subdivided into four classes, viz.: 1. Volitional auto-suggestions. 2. Suggestions of moral education and fixed principles. 3. Instinctive auto-suggestions. 4. Suggestions of the environment. The greater part of the above divisions and subdivisions are explained by their terms. The subdivisions of auto-suggestions, however, require elucidation. Before proceeding to do so I desire to impress a very important fact upon the mind of the reader.

It often happens in the course of experiments in hypnotism that two contrary suggestions will be made at the same time. The invariable result is that great distress of mind is inflicted on the subject, and it often results in bringing him out of the hypnotic state with a severe nervous shock. Where the latter result does not follow, the stronger suggestion necessarily prevails. The importance of this fact will become obvious as we proceed.

1. A volitional auto-suggestion is one which the subject makes to himself before being hypnotized. For instance, if he anticipates the possibility that the hypnotist will place him in a ridiculous attitude, or one repugnant to his sense of propriety, he will resolve beforehand that he will not obey the suggestion. If, then, the anticipated suggestion is made by the hypnotist it will be strongly resisted, and the potency of the resistance will be in exact proportion to the subject's innate sense of dignity or propriety. If that is very strong, and the hypnotist insists upon his suggestion, the subject will be restored to his normal condition.

2. Suggestions of moral education and fixed principles are of a cognate character to the foregoing. These reach the very heart of the subject under consideration. Thus, if a subject is told to do anything that is contrary to the settled principles of his life, he will resist the suggestion with all the force of his moral nature. Consequently, when an immoral or a criminal suggestion is made by a hypnotist, whether it is obeyed or not is purely a question of moral
character. If the subject is strongly intrenched in moral rectitude he will resist the suggestion; and, if the hypnotist persists, the subject will be restored to normal consciousness with a nervous shock proportioned to the infamy of the suggestion. "Strength of mind" is not a factor in the case. Strength of "will," in the ordinary acceptance of the term, has nothing to do with the result. "Will," in the psychic sense, is nothing more nor less than desire. Consequently, if the subject’s desire to obey the dictates of conscience is stronger than his desire to obey the suggestions of the hypnotist, the auto-suggestion must prevail. In other words, there is no such thing in real life as a hypnotist having absolute control of a subject against the will of the latter.

3. Instinctive auto-suggestions are those which arise from the natural desire to protect one’s own life or that of his wife or children. They are by far the strongest auto-suggestions which a criminal hypnotist would have to encounter in an effort to procure the commission of a crime by means of suggestion. It has often been said that a criminal hypnotist would have the power to induce a subject to commit suicide, or to procure an abortion, by means of suggestion. But such a use of that power is obviously out of the question when we consider the inherent strength of the instinct of self-preservation, and the potency of that subjective clinging to the life of the fetus which is the inherent attribute of every mother. Besides, the same instinct of self-preservation would constitute a potent factor in case of an attempt to instigate the commission of a murder. The subject would instinctively reason up to the consequences to himself in case of detection; and, even though his moral principles might not constitute an auto-suggestion of sufficient potency to enable him to withstand the suggestion of a criminal hypnotist, his own instinct of self-preservation would more than likely have that effect.

4. Suggestions of the environment are those suggestions which arise spontaneously in the mind of the subject from his knowledge of the nature of the experiments about to be made, of the character of the persons present, the objects of the experiments, and the desires of the experimenters.

In the whole range of experimental hypnotism there are no auto-suggestions that are more apt to modify results than the suggestions of the environment are. And there are none that are disregarded by a certain class of experimenters with such persistent, aggressive fatality. Indeed, it is somewhat difficult at all times to intelligently eliminate these suggestions; and in a certain class of experiments it is practically impossible. The experiments which we are now considering belong to that class; and it may be set down as an axiom in experimental hypnotism that no laboratory experiment conducted for the purpose of ascertaining whether suggestion can be successfully employed to induce an hypnotic subject to perpetrate a crime is of any evidential value whatever.

When a subject is hypnotized for that purpose he knows that he is among friends. He knows that they are law-abiding citizens who will take care that no harm shall result from the experiments about to be made. He generally knows that he is expected to carry out all suggestions that are made to him. He is very probably aware that he is expected to demonstrate the truth of the proposition that a criminal hypnotist can compel his subject to commit crime. Like all hypnotic subjects he is anxious to win applause—to create astonishment. In short, he knows that he is the central figure in a comedy or farce which is about to be played in the interests of "science," and he feels that he is the "scientist." The inevitable consequence is that he resolves to carry out every suggestion of the hypnotist, knowing that no harm can possibly result.

A paper dagger is placed in his hands and he is told that a certain gentleman present is an enemy who "needs killing." This he is ready to do, and he proceeds to thrust his paper dagger into the heart of his "enemy," amid the applause of the assembled wisdom.

It is obvious that the moral character of the subject can not enter as a factor in an experimental case of this kind. He is simply a player in a farce in which he assumes the rôle of the heavy villain. Moreover, the result could be easily reversed by simply suggesting to the subject that he was expected to disobey the criminal suggestions of the hypnotist. In short, the subject in such experiments will do just what he believes to be expected of him; and the suggestions of the environment will always afford some hint as to that, even if they amount to nothing more than an assurance that it is perfectly safe for him to obey the suggestions made by the hypnotist. It is obvious that laboratory experiments can go no further than the enactment of a farce. No one would dare to place a real dagger or a loaded pistol in the hands of a hypnotized subject and suggest the murder of a real person.°

Space forbids the citation of authorities to sustain the foregoing propositions, although they are numerous.†

It must be obvious to the intelligent reader that laboratory and platform experiments in this line have no possible evidential value. And when we remember that all the hue and cry that has been raised on the subject of "hypnotism and crime" is based upon these same laboratory experiments, it will be seen that the public has been led into an error of enormous proportions and of infinite moment in the administration of criminal justice. This, however, only pertains to the value of laboratory experiments as evidence. It must not be forgotten that while they do not prove that hypnotism can be employed for criminal purposes, neither

° Since the manuscript of this paper was forwarded to the publishers a new book has been placed in my hands, entitled Hypnotism: How it is Done; Its Uses and Dangers, by Dr. James R. Cocke, of Boston. This gentleman had the courage to make a practical experiment in this line. Standing in front of a deeply hypnotized subject, he placed a piece of cardboard in her hands, telling her that it was a dagger, and commanded her to stab him. This command she immediately obeyed with the greatest alacrity. He then handed her an open pocket knife and again commanded her to stab him. She raised her hand as if to execute the command, but hesitated, and immediately had an hysterical attack, which of course put an end to the experiment. The doctor adds: "I have tried similar experiments upon thirty or forty people with similar results." He also states that he made a number of tests to prove that the subject was deeply hypnotized.

† For a fuller discussion of the subject and a collection of authorities, see The Law of Psychic Phenomena, chap. x.
do they disprove that proposition. It simply demonstrates the necessity for eliminating the results of experimental investigation from consideration.

The question of fact still remains: Can hypnotism be successfully employed for the perpetration of crime? My remarks relating to auto-suggestions arising from the moral education and the fixed principles of the subject will have prepared the reader's mind for the only rational answer—viz., it is purely a question of moral character. A criminal hypnotist in control of a criminal subject could undoubtedly procure the commission of a crime under exceptionally favorable circumstances. But a criminal hypnotist would simply waste his energies in hypnotizing a criminal subject; for a man of that character could, without doubt, be just as easily manipulated in his normal condition. Be that as it may, the fact remains that when a man sets up hypnotism as a defense in a criminal trial he proclaims himself a criminal character.

Beyond what has already been said of the worthlessness of experimental investigation, this is the only general proposition that can be predicated with certainty from a knowledge of the fundamental laws of hypnotism. But it practically covers the whole ground.

The first legal question that arises is, How far ought hypnotism to be admitted as a defense when it is pleaded? My answer is that it should never, under any circumstances, be admitted as a defense for the one who is clearly proved to have committed the crime. Drunkenness can not be urged as a defense, and there is infinitely less reason for admitting hypnotism. In the one case a good man may be so far crazed by liquor as to become, in fact, utterly irresponsible. Yet the fact is not admitted as a defense, on the ground that he voluntarily rendered himself irresponsible by getting intoxicated. The hypnotic subject should be held to the same rule and for the same reason; for no man can be hypnotized against his will. This is practically the universal testimony of all the scientific writers on the subject. He voluntarily places himself in the power of a hypnotist whom he more than probably knows to be a criminal character, and he should be held to the same accountability for the results as if he had voluntarily "placed an enemy in his mouth to steal away his brains." Moreover, as I have previously shown, the hypnotized subject will never commit a crime in that state that he would not commit in his normal condition.

The next legal question is as to the admissibility of the testimony of the alleged hypnotic subject in a criminal prosecution of the alleged hypnotist as an accessory before the fact. It is difficult to imagine any legal grounds for the admission of his testimony at all; for if it is true that he was so deeply hypnotized as to be an irresponsible agent in the hands of the hypnotist, he was necessarily in a state that would preclude the possibility of his having any definite recollection of what happened. Indeed, his whole testimony would be open to the suspicion that he was merely reciting the details of a subjective hallucination. In that case his testimony would be literally "of such stuff as dreams are made of"—the "beardless fabric of a vision." Obviously it should have no more standing in a court of justice than an alleged dream. Consequently, if it is clearly proved that he was hypnotized, his own testimony should be excluded as against the other party concerning what happened during the period of his irresponsibility.

This brings up the question so often mooted as to the propriety of hypnotizing a party in court for the purpose of questioning him concerning what happened to him during a previous hypnotization. From a legal standpoint this is a most intensely absurd proposition. Not one of the conditions which give value to human testimony would be present. In the first place, he could not be punished for perjury if he swore falsely; and the instinct of self-preservation would cause him to swear falsely if the truth would militate against him. Moreover, being in a hypnotic state, he would be amenable to control by suggestion, and a cross-examination would utterly confuse him. A cross-examination by a competent lawyer consists largely of artful suggestions in the form of leading questions; and a hypnotized witness would necessarily either be controlled by them or restored to normal consciousness by a conflict of suggestions. Clearly a hypnotized subject can have no legitimate standing as a witness in a court of justice.

I have now briefly examined the salient features of the problem from both the psychological and legal standpoints, and I hope that I have made it as clear to others as it is to me that its psychological features are less repulsive and dangerous to the public than many interested writers have pictured them, and that the few legal problems involved are easy of solution without a resort to legislation. Hypnotism has no legitimate place in criminal jurisprudence. The attempt to thrust it into that field is the result of a determination on the part of interested parties to confine the uses of hypnotism to a select few. This effort has been aided by popular ignorance and criminal instinct, until our courts of justice are now threatened with an inundation of cases involving questions that are new and strange to lawyers and judges and threaten jurors with paralysis. It is humiliating, but it is true, that in the last quarter of the nineteenth century we are threatened with a repetition of the insanity of the seventeenth. The ghost of Cotton Mather stalks abroad at noonday and gibbers from the forum.

THE RECURRENCE OF LYMPHOID HYPERTROPHY IN THE NASOPHARYNX.*

By F. E. HOPKINS, M. D.,
ASSISTANT SURGEON TO THE MANHATTAN EYE AND EAR HOSPITAL.
THROAT DEPARTMENT;
ASSISTANT SURGEON TO THE NEW YORK EYE AND EAR INFIRMARY.
EAR DEPARTMENT.

An apology is perhaps due you for presuming to take up the time of this section by the consideration of any aspect of a subject which has been so long and so thoroughly discussed as that of lymphoid hypertrophy of the nasopharynx. I desire, however, to call attention to one phase of the subject, that of recurrence of the tissue after

* Read before the Section in Laryngology and Rhinology of the New York Academy of Medicine, December 26, 1894.
removal, a point which has not received the consideration it deserves, notwithstanding the voluminous writings upon the general subject, and its free discussion by nearly every one interested in diseases of the throat or ear. The textbooks, for the most part, give but little information upon the point of recurrence; some recent writers even fail to mention it, or assert that there is no such thing. Many physicians—since the operation is now so generally done—thinking there can be no recurrence, and influenced by the brilliant results often immediately following the operation, give the patients and friends too favorable a prognosis as to ultimate results.

I will spare you a repetition of the history of the general subject, long threadbare; nor will I dwell upon the pathology, aetiology, symptoms, or need of the operation, save as a reference may help to elucidate my subject. Nor will it be necessary to allude to a small fraction of the literature from Meyer to Hooper, and from Hooper to the present time. I report herewith a few cases, some of which are from my notes, some were kindly furnished me by friends, and others are from current literature. This list of cases might be much extended, indefinitely so, I think, by personal interviews with those who are operating, although few cases have as yet been put upon record. There are few operators of considerable experience who are not able to recall one or more such cases. This paper does not claim nor purpose to be at all exhaustive. It is designed merely to call renewed attention to a point of importance, with the hope that greater care, both in operating and in the after-treatment, will make recurrences less frequent.

The first three cases which I report are those of patients who were under my care at the Manhattan Hospital.

Case I.—Joseph F., twelve years of age, in poor health, anaemic, and undersized, was referred to me by Dr. Terrillberry from the department for nervous diseases, where the patient was under treatment for chorea. His tonsils had been excised at a dispensary three years previously, and a year following the amygdalectomy he had been operated upon at another institution for naso-pharyngeal obstruction. This latter operation had been done under ether and by a careful and skillful operator. The symptoms of obstruction were entirely relieved for a period of eight months, when they slowly returned. I operated upon this boy, under ether, on May 3, 1894, and removed a large mass of tissue from the vault of the pharynx. He is at present free from symptoms of obstruction, and after operation made a decided gain in every way, including more rapid progress toward recovery from the chorea.

Case II.—Julia F., not a relative of the first, fourteen years of age, the fifth in a family of twelve children. No family history of tuberculosis or syphilis, but the girl’s general appearance was very bad, doubtless largely caused by insufficient food and bad surroundings. At the age of eleven years she had an attack of rheumatism, complicated by a severe sore throat and an acute purulent inflammation of the middle ear, causing perforation of the tympanum. This patient has the high arched palate so often spoken of in connection with this class of cases. I operated upon her under ether during July, 1893, removing both tonsils and clearing out the nasopharynx. The symptoms of obstruction were relieved, the hearing improved, and the patient made a marked gain in health. She came back to the Manhattan on May 5, 1894, with a return of former symptoms. Examination showed a large mass of lymphoid tissue in the nasopharynx and nasal respiration almost impossible. I again operated under ether, and so thoroughly cleaned out the nasopharynx that I feared the patient might suffer from the apparently too radical removal, and so kept her under observation at the hospital for a time. No ill results followed this severe operation (although the most radical I have ever performed), and the patient made rapid improvement in all particulars, including hearing, which had again become impaired. Microscopic examination by Dr. Douglas, the pathologist of the hospital, showed lymphoid tissue only. Early in the present month (December, 1894) the patient returns, and there is found to be further return of the growth. At present it is not sufficient to cause obstruction to nasal respiration, but there is a lack of resonance to the voice and the hearing is again impaired. Why there is a return of the tissue a second time I am at a loss to say, for after the second removal nothing but bare bone could be felt in the vault of the pharynx.

Case III.—J. H., male, six years of age, a child in excellent health and of good family history, was operated upon under ether on May 18, 1893, for the removal of tonsils and of lymphoid tissue of the nasopharynx. There was relief of the symptoms of obstruction, and the hearing improved without other treatment. After a period of about fifteen months, the symptoms, including impairment of hearing, gradually returned. He was brought back to the Manhattan on December 11, 1894. It is interesting to note that upon examination with the finger the growth in the nasopharynx gave one the impression of being a mass of fringelike projections. The center was less prominent than the sides, as if the recurrence had been from increase of the lymphoid tissue remaining around the sides of the former mass, which was removed with the Gottstein curette. There was also obstruction in the nasal passage in this case, which had been overlooked in his former treatment. I operated upon this patient under ether on December 18, 1894, clearing out the nasopharynx, and removing the eechondrosis of the septum which had obstructed the left naris.

A point of further interest in this case, and no doubt also bearing upon the cause of recurrence, is the fact that the child—a fine specimen of a healthy infant in the country, where he was born—was brought to the city at the age of three years, since which time his sleeping-room has been a very small inside room without ventilation, in a ground-floor flat, and this room he has shared with an adult.

The following six cases were furnished me by Dr. J. F. McKernon:

Case IV.—W. R., male, aged eleven years, well nourished, but mental faculties not up to the average.

Was operated upon under ether by Dr. McKernon October 2, 1892, for the removal of tonsils and lymphoid hypertrophy of the nasopharynx. A large mass of tissue, completely filling the vault of the pharynx, was removed with the Gottstein curette. After removal the finger was swept around the vault, and it was found to be free from all lymphoid hypertrophy.

A little more than a year later, October 12, 1893, the boy was brought back to the doctor with a return of the symptoms which called for the previous operation. Upon examination a large mass of lymphoid tissue was found well anterior in the vault of the pharynx. The Quinlan forceps was used without ether, the operation being finished with the Gottstein curette for the posterior wall of the pharynx, and a large mass of tissue, about two thirds the size of the former growth, was removed. Since then, up to May 5, 1894, the patient has been
entirely free from the distressing symptoms caused by the presence of the growths. A peculiar point about this patient was his extreme dullness, both with regard to books and in playing with other children.

Case V.—E. K., nine years of age, brother of W. K., just reported, was brought to Dr. McKernon October 2, 1892, suffering from naso-pharyngeal catarrh and deafness of left ear. Examination showed both tonsils enlarged, and a mass of lymphoid tissue in the nasopharynx, situated almost entirely to the left of the median line, and extending well forward in the vault and down upon the posterior pharyngeal wall. Under ether the tonsils were removed and the nasopharynx was thoroughly cleared out. On September 26, 1893, this patient was again brought to the doctor suffering from a return of all the former symptoms, except the deafness. Examination revealed a mass of lymphoid tissue occupying the old site—i.e., to the left of the median line, both in the vault of the pharynx and upon its posterior wall. Quinlan forceps followed by the Gottstein curette was now used, removing a mass nearly as large as the original one.

Patient last examined May 17, 1894, when he was free from all former symptoms. This boy was well nourished, and except for the local trouble mentioned seemed in perfect health both before and after the operation.

Case VI.—M. B., female, seven years old, well nourished, fleshly, and large for her age. Was brought to Dr. McKernon suffering from deafness in both ears and a constant desire to clear the throat and nose. Examination showed both tonsils enlarged and vault of pharynx well filled with lymphoid tissue which extended down upon posterior wall of pharynx. On January 19, 1893, under ether, tonsils were removed and vault of pharynx cleared with Löwenberg forceps, which was used because of the extreme narrowness. The Gottstein was then used on posterior wall of pharynx, when examination with finger showed vault and wall completely freed from lymphoid tissue. Eleven months later this child was brought back to the doctor suffering from catarrh of nose and throat, but no return of deafness. Examination of nasopharynx revealed a mass of tissue present which was about half as large as the growth previously removed. This was removed without ether by use of the Quinlan forceps. Examination of the vault of the pharynx on November 17, 1894, shows no recurrence. Patient in excellent health both before and after operation, but had always slept in a room with no ventilation.

Case VII.—A. A., male, aged six years, was brought to the doctor for relief of deafness and nasal obstruction. Was operated upon under ether, the tonsils being excised, and nasopharynx cleared of the mass of tissue present by use of the Gottstein curette. There was complete relief from all symptoms for a period of ten months, when the old train of symptoms, except the deafness, returned. Examination of vault of pharynx showed a mass of lymphoid tissue upon the old site. He was now given ether and the Gottstein used to remove the mass.

Up to April 3, 1894, there was no recurrence. Hygienic surroundings of this patient were very bad, apartments lacking ventilation, being a ground-floor flat.

Case VIII.—E. K., female, nine years of age, an anemic child from a tenement house, was operated upon at the Manhattan Hospital early in 1893 for the removal of lymphoid tissue from the nasopharynx, the Quinlan forceps being used. She was brought back to the hospital in July of present year suffering from naso-pharyngeal obstruction. Examination showed the presence of a mass of tissue well anterior in the vault. Under ether this mass was removed with the Quinlan forceps, followed by the Gottstein. The patient has not been seen since the operation.

Case IX.—E. C., female, three years and a half of age, an anemic and pasty-looking child. Was operated upon by a prominent specialist in London for the removal of lymphoid tissue from the nasopharynx. The doctor gave a favorable prognosis, stating positively that there would be no recurrence. Eleven months later, in October, 1894, the child, suffering from a return of former symptoms, was examined, and small groups of lymphoid tissue were found in the vault and upon the posterior wall of the pharynx. The growths were removed under ether, and by the use of the Löwenberg forceps followed by the Gottstein. In this case the hygienic surroundings were of the best. The parents were wonted up to great indignation over the outcome of the case, since they had been promised that the first operation would be final.

Case X.—Dr. Butts (1) has reported one case, and kindly given me the notes of another. The first was that of an English girl, sixteen years of age, who gave a history of having been operated upon three times under chloroform before coming to this country. Dr. Butts operated upon this patient three times, at intervals of two months, completely removing all the tissue at each operation. Twice the lymphoid tissue had returned on the same site. The last operation was apparently successful, as four months elapsed without return, when the patient was lost sight of. Microscopic examination of the tissue removed showed it to be lymphoid hypertrophy.

Case XI.—His second case was that of a boy aged twelve years. Operation was done under ether on October 24, 1892; tonsils were removed and naso-pharynx cleared of obstructing lymphoid tissue. Nothing more was heard of the case until March 26, 1894, when the child was brought to the doctor with a return in a mild degree of his former symptoms. Examination with the rhinoscopic mirror revealed a very perceptible return of the mass of tissue in the vault of the pharynx. About two months before this the child had what was pronounced to be diphtheria, but in a mild form. From this time it was noted by the parents that there was a gradual return of the old symptoms.

Case XII.—The following case is from the notes of Dr. Emil Mayer: Frank H., aged three years. Lymphoid hypertrophy of the vault of the pharynx. The mass was removed under ether by means of Gradle forceps and Gottstein curette, leaving the vault perfectly clear, and resulting in an entire subsidence of all symptoms of obstruction. The child remained well for a period of two years, when, the symptoms of obstruction again returning, a second mass of lymphoid tissue was removed under ether.

Dr. Delavan (2) has reported an interesting case in which recurrence occurred twice.

Dr. Jonathan Wright (3) also has reported a case.

Dr. Lavrand (4), of Lille, has reported two cases of undoubted recurrence in children, aged respectively six and nine years.

Dr. Barrett (5), vice-president of the Australasian Medical Congress, said, in discussing the subject of lymphoid hypertrophy of the nasopharynx at the session in 1892, that he had seen growths return where he had had satisfied himself by after-examination that the removal had been thorough; in one case the recurrence had occurred three times. Dr. Quinof (6), at the same meeting, after urging the importance of thorough removal, remarked that he had occasionally found that small tags, which were quite imperceptible to the eye, had afterward blossomed into vegetations full grown, though certainly not very extensive.
In the discussion of a paper upon Post nasal Growths in Children, read by Mr. Owen (7) before the Harveian Society of London, Mr. Dutlin said that, although he had operated for removal very many times, and many of his cases had been under observation from one to seven years, he was cognizant of only one case in which there was un-
doubted-recurrence after complete and careful removal.

Mr. Mark Hovell, at the same discussion, mentioned a
case which had been operated upon twice before she came
under his care, and in which he had found it necessary to
repeat the operation three times after intervals of a few
months, on account of redevelopment of the growth.

Dr. Seames Spicer said recurrence occurs only after
imperfect removal.

Dr. Felix Semou said that, in his experience, in no class
of cases was a repetition of the operation more frequently
required than in those in which the finger-nail had been
used as the instrument for removal. Mr. Lennox Browne
said that recurrence was rare and mentioned no cases. This
discussion is of some interest, since it may be taken as an
expression of English specialists upon the subject, so many
men of prominence having taken part in it.

Woukes (8) says: "I do not believe in the recurrence of
the growths after thorough operation. When this ap-
pars to happen it is due to some of the smaller ones hav-
ing escaped removal; these, developing later on, are then
looked upon as a return of the disease."

Hooper (9), in his paper on Adenoid Vegetations in
Children, their Diagnosis and Treatment, stated that "the
growths do not recur after removal."

McBride (10) does not mention the possibility of re-
currence.

J. Solis Cohen (11) says: "There does not seem to be
any disposition to repulubilation of these vegetations after
thorough evulsion or destruction."

MacDonald (12), in his work, gives no special informa-
tion on the subject in hand.

Burnett's (13) recent work is the most unsatisfactory of
all, for we are told that "moderate evertting or the biting
or burning off of a few of the most prominent nodules,
combined with the use of iodine and the proper treatment
of the whole naso-laryngeal tract, is sufficient in the great
majority of cases."

Dr. James B. Ball (14), in a text-book just published in
London, says: "Once thoroughly removed, adenoid
vegetations do not recur. When, as sometimes happens, a
second operation is required, this is due to small vegeta-
tions having been left behind, which swell up on removal
of pressure from the surrounding masses."

Dr. Ingals (15), in his work, speaking of the use of
such agents as galvano- cautery, scraping with the finger-
nail, etc., says: "The operation thus is usually less com-
plete than when done by suitable forces, and therefore
recurrence is more likely to take place."

Referring now to writers whose articles have appeared
in the recent journals, we have the carefully prepared paper
of Dr. De Roaldes (16), of New Orleans, who quotes and
indorses Hooper's statement that "the growths do not re-
curr"; Dr. J. Morrison Ray (17), of Louisville, who says:

"If once thoroughly removed, there can be no return";
Dr. W. Meyjes (18), of Holland, who states that "the
opinion that the adenoid vegetations will grow again after
removal is false and only caused by the fact that the tissue
was not completely removed"; and Dr. A. B. Thrasher
(19): "Under complete anesthesia there is time to entirely
exiripate the growths so that very rarely will a second op-
eration be required."

The foregoing references may be taken as fairly rep-
resentative of what writers have stated upon the question of
recurrence. Thus it is seen that if we depend upon this
source alone for information we are likely to be misled. It
is but just to say, however, that a few have laid greater
stress upon the possibility of recurrence. Among these,
Bosworth (20) refers to Meyer's report of thirteen cases of
recurrence in his first series of a hundred and two cases.
Meyer made this report as long ago as 1881, eleven years
after his first paper. French (21), too, insists most
strongly upon complete removal of the tissue, that recur-
rence may be prevented. It must be admitted that recur-
rence does take place, and that it occurs more frequently
than the text books would lead one to infer; also that it
may happen even though every vestige of the tissue has
been removed from the nasopharynx.

It is probable that many more cases of recurrence will
be mentioned within the next few years than have yet
been put upon record. The rapid method of operating is
popular, and so many men are now doing the operation
that the chances for imperfect removal are largely in-
creased, involving the greater probability of recurrence.
If this be true, it is well that the fact be clearly under-
stood, that we may be more guarded in prognosis as to
ultimate results, and the more carefully make use of such
measures as shall tend to prevent recurrence.

What, then, are the practical deductions to be drawn
from our consideration of the subject? I confess I have
but two points to offer. I would join with those who in-
sist upon complete removal of the tissue—under an anes-
thetie in children up to fifteen years of age—and suggest
that each case be given more attention in the after-treat-
ment.

As to the time for operating or the preliminary use of
tonics, Dr. French (21) well says "the sooner the operation
is performed the better, for there can be no more valuable
tonic than that which results from re-establishment of nasal
respiration." Then one must assure himself that there is
no obstruction in the nasal passages, or, if present, correct
it, that there may be no further hindrance to nasal respira-
tion. After operation the child should take syrup ferri iodidi
for some weeks, with whatever added remedy may seem to
be indicated, bearing in mind the possibility of constitu-
tional taint of rheumatism, tuberculosis, or syphilis. A
further point of prime importance is that of the hygienic
surroundings of the patient, particularly the child's sleep-
ing room. We have conditions at opposite ends of the
social scale productive of similar results. The poor often
live in small, overcrowded, and ill-ventilated rooms; the
rich frequently in overheated and also ill-ventilated apart-
ments. The evil effects upon the patient are similar in the
two cases. This difference between the temperature of the overheated houses and that out of doors presents the most constant and common source of frequent coryzae. These conditions ought as far as possible to be corrected, because "this lymphoid tissue evinces a strong tendency to augmentation in bulk upon slight provocation, so that any cause of increased blood supply will be sufficient to start renewed hypertrophy." (12). If, then, the child is again exposed to the same conditions which caused the hypertrophy, we must expect that recurrence will sometimes happen, and especially in those cases where the operation has not been thorough enough.

ASPERMATISM.

By J. HENRY C. SIMES, M. D., PHLadelphia.

Cases which may be classed under this head are not often met with; even the surgeon who limits his practice to the treatment of genito-urinary surgery sees them but seldom; they may, however, be encountered, and are interesting both pathologically and physiologically.

This affection, which is necessarily a condition that must result in sterility, is one in which sexual connection is completed but not perfected. That is to say, there is desire, coition, penetration, but no ejaculation of the seminal fluid from the urethra into the vagina. A classification of the affection has been made which is based upon the etiology of the lesion: Organic, when it arises from some obstruction of the ejaculatory ducts or urethra; atonic, when depending upon diminished or lost sensibility of the spinal ejaculatory center; anesthetic, when the nerves of the penis have lost their sensibility; and psychical, when the inhibitory action of the brain over the center for seminal ejaculation is such that the act is arrested. A more simple classification would be those cases which are dependent upon some evident pathological lesion, and those which are due to functional causes—that is, the pathological condition which occasions the affection has not yet been demonstrated. The majority of cases which are met with may be placed under the first class, since it will be found that by a careful examination it is possible to discover some pathological condition which will account for the lesion. The cases in which no pathological change of any kind can be discovered after a most careful examination are occasionally met with, but, while no pathological lesion is evident, there is generally, in going over the history of the patient, some indication which will account for his present condition. The cases in which no pathological change is evident, and the history gives no clue to the cause for the existing condition, are very seldom seen, but there have been such cases reported, and the following may come under this class:

X., born in Ireland, twenty-six years old, a blacksmith, unmarried. General health very good; the only sickness he has had any recollection of was an attack of typhoid fever, which occurred three years ago, from which he made a complete recovery. In regard to his sexual power, he states that he has the desire to have sexual connection, but whether this desire is as great with him as it is with other men he is doubtful, from the fact that he is not so often inclined as many of his friends are to perform the act; however, when the opportunity offers he is always willing to accept it. He experiences no difficulty in having an erection of the penis when wishing to have sexual connection, and there is no trouble in entering the vagina. There is some pleasure during the copulating act, but it is not very great, being, as he says, a feeling of satisfaction more than pleasure. He ceases the act not because there has been a discharge of semen, but because the erection of the penis goes down, and he experiences a feeling of exhaustion; this takes place in about the normal time. He is most positive that there has never been any discharge of seminal fluid, or, indeed, any fluid during his attempts at sexual connection. There has never been any ejaculation of semen by performing the act of masturbation; in fact, there never has been any desire to commit this act during any period of his life. Nocturnal seminal emissions he has never had, and lascivious dreams have been extremely seldom, never accompanied with a seminal emission. There has never been any sexual excess committed in any way. There is no evidence or history of any venereal disease. No recollection of ever having any injury or disease of the genital organs. Examination.—He is a very well developed man, rather undersized, and from his occupaiion, a blacksmith, his muscular development is especially good. Hair on the face and body fully up to the normal amount. The external genital organs appear normal; the penis is of normal size and firmness, and he states when erected it is of good size and hardness; the glans penis is partially covered by the prepuce, which may be completely retracted so as to uncover the glans; the testicles are of
normal consistence, well developed, and rather above than below the ordinary size; the scrotum is not at all relaxed, but well contracted; the cord gives every indication of being in a normal condition; the vas deferens can be felt quite distinctly, and there is no evidence of any enlargement of the veins. A full-sized sound passes along the urethra into the bladder without any difficulty, no obstruction being met with, and the normal amount of sensibility is evident when the instrument passes over the prostatic region of the urethra. At no time during his life has there been any difficulty in urinating; micturition has never been abnormally frequent or painful. There has never been noticed any deposit in the urine, even after sexual connection; this has been looked for, but was always absent; nor after sexual connection has there been noticed any flow of seminal fluid or any fluid from the urethra. As far as could be ascertained by examination, there is no indication of any abnormal condition of the prostate or vesiculae seminales.

This examination is certainly negative, and if it were not for the positive statement of the man that he has never, under any circumstances, had an ejaculation of seminal fluid, the only conclusion to be drawn from the examination would be that all the functions of the sexual organs ought to be performed in a normal manner.

This case certainly can not be placed under the class which has some evident pathological lesion as an aetiological factor, but necessarily comes under those cases in which the pathological change is not demonstrable—the so-called functional disorders. Neither do I think it can be classed with the atomic form of aspermatism, in which there is said to be a loss of power in the contractility of the muscles connected with the act of ejaculating the spermatic fluid, since in these cases there occurs at intervals the discharge of semen during sleep, and also patients who complain of this form usually give a history of venereal excess, of having practiced masturbation to excess, or of having had frequent attacks of gonorrhoea, none of which are applicable to our case. Is it to be classed under anaesthetic aspermatism—those cases in which the sensitive nerves of the penis have partially or completely lost their power of conducting the sensory impressions excited by the friction of the penis against the walls of the vagina to the lumbar division of the spinal cord? Our patient might come under this class, but in reviewing the cases which are so classed they all, without exception, state the patient experienced at intervals nocturnal pollutions; therefore this circumstance would exclude our patient from this class. Finally, is it to be classed under psychical aspermatism—those peculiar cases in which there is never to be found any organic pathological condition to account for the complaint? And the history of the patient's life gives no clue to the cause of his condition. This, indeed, seems the only class in which the case may be located. We have, so far as it is possible to ascertain, all the conditions necessary for sexual congress—desire, erection, and power; a development of the external genital organs which appears in every way capable, and nothing abnormal could be determined to exist in connection with the internal organs of generation. Everything is present but the seminal fluid, and it is this fact which makes the case differ from all others in the above classifications, so that I can not satisfactorily place it under any of them, but would consider it a case in which there is no secretion of the spermatic fluid, and as a consequence the sexual passion is necessarily not perfectly developed; or it may be more correct to say that there is a partial delay of development of the sexual passion, and as a result no secretion of the semen. Why such seemingly perfectly developed testicles have not performed their physiological function it is difficult to determine, but such seems to be the fact, and I am inclined to the opinion that under favorable circumstances—that is, a congenital married life, which as yet the patient has not experienced—the testicles would very probably assume their proper physiological function.

In considering this case, of course, the question of the truthfulness of the man's story is to be determined, and in this respect I have no reason to doubt him; indeed, quite the opposite. There is no motive for him to practice any deception, rather otherwise, since he is contemplating marriage, and wishes an opinion as to the propriety of contracting such an alliance; therefore, one would naturally suppose that there would be more of an incentive to deceive in the opposite direction. Again, may he not be mistaken as to the fact, and that there is a discharge of seminal fluid of which he is not conscious! But the most careful questioning does not permit this doubt; he is so very positive upon this point that there seems to be no reason why his statement should not be accepted as true. The patient is observing and quite intelligent, much more so than those usually met with in his position.

In answer to the question of the propriety of marriage in this case, I had a hesitancy in expressing my opinion. If one is satisfied, in a given case, that there exists a permanent sterility, no hesitation should be shown in giving a positive opinion as to the non- advisability of contracting marriage. Curling has very well and forcibly expressed himself upon this point; he writes as follows:—"That a man who is unable to fulfill the command to be 'fruitful and multiply' is right in disappointing the hopes and periling the happiness and probably health of a woman can not, I think, be maintained by any casuist, and in some of the foregoing cases I have felt it my duty to give advice in accordance with this opinion." Where a doubt exists, however, as in this case, as to the permanency of the sterility, then one is justifiable in hesitating to condemn a man to a life of celibacy; but I do not think the surgeon should take the responsibility of the result; rather let him state the probabilities pro and con to the patient, and it will be for him to decide.

2033 Chestnut Street.

The Gross Medical College, of Denver.—The faculty announce a course of "special and popular" lectures, to be given every Friday evening. The first lecture was given on January 15th by Dr. E. Jackson, professor of ophthalmology in the Philadelphia Polyclinic, on Ways in which the Eye Fails to Meet our Modern Requirements.

New Medical Baronets.—The Hospital announces that Dr. J. Russell Reynolds and Mr. John Eric Erichsen, of London, have been made baronets.
INSUFFLATION OF AIR IN TUBERCULOUS PERITONITIS.

The Revue de chirurgie for December publishes an article on this subject by M. Folet, of Lille, who remarks that since the day when, by a fortunate mistake in diagnosis, Sir Spencer Wells opened a tuberculous peritonitis, and especially since asepsis has rendered the opening of the abdomen a relatively benign operation, operative intervention has often been practiced, whether by design or under a misapprehension, in tuberculous peritonitis. König was the first to propose laparotomy in such cases as the most efficacious means of combating the disease. The author himself has performed laparotomy twice in peritoneal tuberculosis of an ascitic form, with good results. It is in the ascitic forms, he says, subacute or chronic, general or encysted, that the results are most favorable. In the dry and fibro-plastic forms, with infiltration and thickening of the omentum, the results are not so favorable.

The question of the mechanism of recovery, says M. Folet, is a hypothetical one. It is probable that ascites, in involving the blood-vessels, hinders absorption of the inflammatory products; furthermore, the ascitic fluid favors the spread of the disease, since it constitutes an excellent medium of culture, although the microbiological examinations of the serosity rarely show the presence of bacilli. The evacuation of the liquid, by allowing the formation of adhesions which stop the growth of tubercles, may also be an essential element of cure; finally, the favorable action may perhaps result from the fact that we remove the microbic pneumoniae accumulated in the ascitic liquid, the absorption of which products might facilitate the propagation of the disease to other organs. All this, however, he says, is vague, uncertain, and not sufficiently demonstrated.

Another theory is tenable, says the author, which is that in all these operations some physicians practice only that evacuation of the liquid which necessarily follows abdominal section, while others supplement this evacuation with applications intended to modify the serous surface, such as detersive irrigation with boiled water; "modifying" irrigation with salt water or with solutions of thymol, boric acid, salicylic acid, corrosive sublimate, carbolic acid, zinc chloride, or the like; applications of camphorated naphtha, tincture of iodine, or powdered iodiform; cleansing and curetting, with the application of iodiform gauze or gauze saturated with salol; and peritoneal drainage. All these forms of intervention have given good results. As they have but one point in common—namely, the free opening and exposure of the peritoneum, it seems logical to suppose, says the author, that contact with the air, the draining, and perhaps the influence of light, are capable of acting directly on the tuberculous processes and of killing the anaerobic bacilli, perhaps sometimes by causing the death of anaerobic microbes the association of which with the bacilli favors their multiplication, sometimes by favoring the development of an antagonistic anaerobic microbe. From this reasoning the conjecture was obvious that, in cases of tuberculous peritonitis with ascites in which for any reason abdominal section was out of the question, success might follow tapping and the insufflation of air. The author relates the history of a case in which he had occasion to insufflate air (not filtered), and obtained excellent results. He also relates another case which had come under the observation of Professor Moorhof, of Vienna, who resorted to the same method with equally good results. In both cases the insufflation of air caused no accidents, and appeared to give favorable results immediately, results which lasted for at least eight months.

The question arises as to whether or not tuberculous peritonitis may be cured spontaneously. In reality, says M. Folet, the cure of tuberculous peritonitis is always spontaneous, even after surgical intervention. Laparotomy never removes and does not destroy the diseased tissues; it only puts the peritoneum in a favorable condition for reaction, which favors the disappearance of the existing lesions. Nevertheless, among the ascitic forms of peritonitis—which give the largest number of recoveries in cases of operative intervention—there are cases in which recovery takes place without any surgical interference, although these are not cases where one has to deal with true peritonitis or with an invasion of the peritoneum by bacilli, but with a peritoneal effusion due to compression of the portal vein by a group of intra-abdominal ganglia. In the same way that cervical bacillary adenitis is dispersed, spontaneously or under the influence of an energetic iodine treatment, the intra-abdominal ganglionic hypertrophies may become dispersed, and the ascites, which has been caused by the circulatory obstacle, disappears. However, it may be observed that, at the present time, recovery as a result of operative intervention has been observed, not only in cases of ascitic effusions, but also in peritonitis with flocculent or sero-purulent liquid, with false membranes, with cohesion of the intestinal coats, and with granulations strewn over the visceral layer or on the surface of the intestine; in dry bacillary peritonitis; in peritonitis connected with tuberculosis of the ovaries and of the Fallopian tubes—all these lesions having been ascertained to exist where laparotomies have been performed. Recovery from tuberculous peritonitis, says the author, is not only apparent, but may be complete from an anatomical point of view. Laparotomy is certainly the preferable operation, says M. Folet, but under certain conditions the physician may resort to the anaodyne and efficacious method of insufflation of air.

ONE OF THE BEAUTIES OF THE BRITISH VIVISECTION LAW.

In the British Medical Journal for January 12th we find an editorial article which informs us of certain perplexities that are troubling some of our British brethren as a consequence of
the vivisection law, but we fancy that a little humor was meant to be apparent between the lines. It seems that under the law in question no painful operation in the nature of an experiment is allowed to be performed upon an animal without the use of an anesthetic, except under the protection of a special certificate stating that insensibility can not be produced without necessarily frustrating the objects of the experiment. The more prudent and conscientious of those of our British colleagues who occupy themselves with such procedures as experimental inoculations, whether for the purpose of diagnostiating glands or tuberculosis or for that of propagating vaccine, are troubled apparently as to whether or not the law was really intended to apply to such operations as the prick of a hypodermic needle and the scarification of vaccinal inoculation. The writer of the editorial seems to assume—and in so doing it appears to us is perfectly warranted—that to anesthetize a guinea-pig upon which a simple puncture was to be inflicted would be to violate the spirit of the law while conforming to the letter. Few would be found to contend, he thinks, that the simple prick of a hypodermic needle was the kind of pain that the framers of the act had in view, and he suggests that the only reason for looking upon these experiments as coming under the law would be the fact that the inoculation subjected the animal to the subsequent annoyance of disease. This he admits to be true theoretically, but goes on to remark that animals so inoculated never afford any evidence of pain whatever, and adds that it is certain that the thousands of animals that have been infected with tubercle by means of inoculation or feeding have suffered no pain at all. He thinks, moreover, that it would be impossible to prove that animals infected with the more acute febrile conditions had suffered pain. We learn from the article, further, that the Council of the British Institute of Preventive Medicine, when it undertook the preparation of diphtheria antitoxine, considered the relations of its work to the vivisection law, and came to the sensible conclusion that the process, not being an experiment, and not calculated to give pain, did not come within the law; and that this view has practically been adopted by the law officers of the Crown. The writer questions if the time has not arrived for putting a reasonable interpretation upon the law and incurring the risk of a prosecution, and advises a little boldness as the best course to pursue, and the one most likely to be successful, as the only alternative of the unpromising task of trying to get the law amended by the House of Commons in the present state of public opinion.

THE TREATMENT OF SMALL-POX WITH ANTITOXINE SERUM.

In the Abstract of Sanitary Reports for January 18th there is a preliminary report by Passed Assistant Surgeon J. J. Kin- youn, of the Marine-Hospital Service, on the treatment of small-pox by injections of serum from calves that had been recently vaccinated. After the local manifestations of vaccination had disappeared from the animal, and it seemed to all appearances sound and well, blood was withdrawn from a vein, and allowed to stand for twenty-four hours in order that the serum might be drawn off. Some of this serum was filtered, and two cubic centimetres of the filtered and unfiltered serum respectively were added to thirty-five minims of pure vaccine lymph. Each mixture was used to inoculate unvaccinated heifers, and, as it did not produce any symptoms, it was inferred that the serum completely neutralized the lymph.

The serum was then administered to a negro, aged twenty-eight, suffering with confluent small-pox, in a dose of fifteen cubic centimetres hypodermically. In an hour the respiration became deeper and the pulse stronger and fuller. Two more doses of serum were administered on the same day, and one dose was given on the following day, so that in all sixty cubic centimetres were injected. The patient died in three days after the first injection, but the attending physician is reported as having thought that the serum had prolonged life for seventy-two hours. In a second case, also in a negro, a hundred and five cubic centimetres were administered in the course of two days, and the patient recovered.

The serum, it is said, tends to increase the volume of the pulse, and there is a modification in the variolous eruption. Maurice Raynaud's experiments have shown that the blood serum of an animal on which immunity has been conferred destroys the potency of vaccine lymph, and under certain circumstances renders an inoculated animal insusceptible to vaccinia.

These results would suggest that the serum possesses an antitoxic property, and they may be held to justify Dr. Kin- youn's use of the serum for therapeutic purposes.

MINOR PARAGRAPHS.

THE INFLUENCE OF SMALL-POX IN PARENTS ON THEIR CHILDREN'S RECEPTIVITY FOR THE DISEASE.

The Revue internationale de médecine et de chirurgie pratique for December 25th contains an abstract of an article on this subject contributed by M. B. Auche and M. Delmas to the Archives cliniques de Bordeaux. The following conclusions, the writers say, are drawn from a certain number of personal observations: 1. Small-pox in the father seems to have no influence on the receptive condition of the child in regard to vaccination. 2. Small-pox in both father and mother before conception does not act on the child's condition any more decidedly than it does when the mother alone has the disease. 3. Small-pox, when it precedes pregnancy, sometimes establishes immunity in the child. 4. If small-pox breaks out during pregnancy, several alternatives are possible: a—the child is in the stage of incubation, and it is susceptible to the vaccinal virus up to about five or six days before the appearance of the eruption; b—it is born with small-pox or with marks, and it is evidently resistant to the vaccine; c—it has not had, has not, and will not have small-pox. If it is born during the period of incubation, of invasion, of eruption, or even of putation in the mother, it may be vaccinated successfully. If it is born during desiccation and convalescence, it is sometimes resistant, although often susceptible to the vaccinal virus. At a later period immunity is generally conferred upon the child, although not at once; it seems to require a certain length of time in order to be produced. Once it is acquired, the immunity is
transitory, and lasts only from a few months to two or three years. The preceding statements may probably apply to immunity against small-pox as well as to that against vaccination.

A NEW METHOD OF INDUCING LOCAL ANÆSTHESIA.

The Gazette de gynécologie for January contains an abstract of an article by M. Létang, which was published in the Polon médical. The method described consists in injecting into the region to be operated on a liquid the temperature of which is considerably below the freezing point. After several trials M. Létang has found that glycerin, oil, and pure water can be employed in considerable quantities without danger, and that the rapid injection of several cubic centimetres of water at 34° F. provokes slight lesions in the tissues, but that this effect is prevented if a drop of ether is added to the water. The following solution keeps well, and may be prepared quickly and aseptically with boiling water: Boiled distilled water, six ounces; pure neutral glycerin, three ounces; ether, ninety grains. Ten injections of one hundred and fifty grains each of this solution may be administered to an adult without any inconvenience. In order to obtain a proper temperature, a carbouc-acid apparatus may be used, which will produce an intense cold in a few seconds; also a syringe for interstitial injections, provided with a thermometer the reservoir of which is plunged into the liquid, and the index-rod of which, resting in the cylinder of the syringe, may be examined easily. It requires about forty seconds to bring about the proper temperature, which is 14°. Bulbs of ethyl chloride also may be employed to produce the right degree of cold.

THE STUDY OF PHARMACY.

The Pharmaceutical Era has begun the weekly publication of a series of articles entitled The Study of Pharmacy. The Era announces that these articles are prepared by the foremost writers and teachers in pharmacy, and are designed to afford a logical, systematic, and thorough ground-work of education in pharmacy to persons who have not had the most desirable advantages for securing such an education. The introductory article, by Dr. Charles Rice, for a copy of which in pamphlet form we beg to thank our excellent contemporary, deals with the history of pharmacy in the United States, with the pharmacopoeias of the world, and especially with our own pharmacopoeia. Dr. Rice's writing is always readable and of sterling value, and the article in question should command the attention of a wide circle of readers, not only in the profession of pharmacy, but in that of medicine also, for, says the editor of the Era, "these two professions have marched hand in hand in the development of our pharmacopoeia." Of late years the teaching of pharmacy in New York has made great advances. Not the least conspicuous among the tokens of its progress is the recent opening of the fine new building for the College of Pharmacy, said to be the finest of its kind in the world. It is gratifying that the colleges of pharmacy have such efficient auxiliaries as the pharmaceutical journals, of which the Era is a worthy example.

THE UNION MÉDICALE.

This journal, which has long stood among the foremost of the Paris medical periodicals, has, with the advent of the new year, made some notable changes in its appearance and in the manner of its publication. Formerly it was an octavo issued three times a week, and occasionally four times; it has now doubled the size of its page, which has been made double-col-

The Cleveland Medical Society held its annual meeting on Friday evening, the 11th inst. Officers for the ensuing year were elected as follows: President, Dr. William E. Wirt; vice-presidents, Dr. A. F. House and Dr. Henry S. Upson; recording secretary, Dr. W. F. Brokaw; corresponding secretary, Dr. Frank S. Clark; treasurer, Dr. N. Stone Scott; librarian, Dr. William E. Bruner; censors, Dr. M. Rosenwasser, Dr. Howard S. Straight, Dr. L. B. Tuckerman, Dr. A. J. Cook, and Dr. W. J. Scott; pathologist, Dr. A. P. Oltmacher; trustees, Dr. H. G. Sherman, Dr. C. Gentsch, and Dr. C. F. Dutton. In the address by the retiring president, Dr. W. H. Haminston, it was stated that the society had 291 members, and that the average attendance at the meetings during the year had been 185, so that in the matter of attendance it was second to no medical society in the United States. The meetings are held once in two weeks.

The Late Dr. Henry Goldthwaite.—At a special meeting of the Medical Board of the City Hospital held at the New York Academy of Medicine on January 17, 1895, the following preamble and resolutions were unanimously adopted:

Whereas, We have learned with deepest regret of the death of our revered colleague, Henry Goldthwaite, M.D.; therefore Resolved, That in the death of Dr. Henry Goldthwaite we have lost a valuable and useful friend. His heart was warm and benevolent; to the poor and suffering he was devoted and consoling. With the highest sense of duty, he never spared himself, but always met with manly courage the responsibilities of his position. He was a wise counselor, a warm and valued friend, a colleague of acknowledged forethought and wisdom, and a man of inlexible honesty and pure and upright character. Resolved, That we deeply sympathize with the widow of the deceased and the other members of the family; and that a copy of these resolutions be transmitted to them, and that they be published in the medical journals.

[Signed.] Alex. W. Stein, J. H. Allen, Committee.

J. A. Andrews.

J. R. Hayden, M. D., Secretary of the Medical Board.
The New York State Medical Association.—The eleventh annual meeting of the Fifth District Branch will be held in Brooklyn on Tuesday, May 28th, under the presidency of Dr. Austin Flint. All fellows desiring to read papers should notify the secretary, Dr. E. H. Squibb, P. O. Box 769, Brooklyn.

The Columbia College School of Medicine.—It is announced that Dr. Richard Cunningham, of the class of 1888, has been appointed Alumni Association fellow in physiology.

A Reception in Honor of Dr. Emil Holub was given on Friday evening, the 25th inst., by Dr. Carl Beck at his house, in East Thirty-first Street.

Change of Address.—Dr. Frank C. Todd, from Minneapolis, Minn., to the corner of Seventh and Main Streets, Fort Worth, Texas.

Army Intelligence.—Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from January 13 to January 19, 1895:

Smith, Joseph R., Colonel and Assistant Surgeon General, will be relieved from duty as Medical Director, Department of the East, to take effect about February 5, 1895, and will proceed to his home, where he is authorized to await retirement.

Naval Intelligence.—Official List of Changes in the Medical Corps of the United States Navy for the week ending January 19, 1895:

Curtis, L. W., Passed Assistant Surgeon. Detached from the Naval Hospital, Chelsea, Mass., and placed on waiting orders.

Stone, L. H., Passed Assistant Surgeon. Ordered to the U. S. Steamer Alliance. January 22d.

Pigott, M. R., Passed Assistant Surgeon. Ordered to the U. S. Steamer Olympia.

Marine-Hospital Service.—Official List of the Changes of Stations and Duties of Medical Officers of the United States Marine-Hospital Service for the Fifteen Days ending January 15, 1895:

Perry, T. B., Passed Assistant Surgeon. To proceed to Delaware Breakwater Quarantine Station for temporary duty, and to join station (Cape Charles Quarantine) upon completion of same. January 14, 1895.

Society Meetings for the Coming Week:

Monday, January 28th: Medical Society of the County of New York; Boston Society for Medical Improvement; Lawrence, Mass., Medical Club (private); Cambridge, Mass., Society for Medical Improvement; Baltimore Medical Association.

Tuesday, January 29th: Medical Society of the County of Onondaga (semi-annual—Syracuse), N. Y.; Boston Society of Medical Sciences (private).

Wednesday, January 30th: Auburn, N. Y., City Medical Association; Berkshire, Mass., District (Pittsfield), and Middlesex, Mass., North District (Lowell) Medical Societies; Gloucester, N. J., County Medical Society (quarterly).

Friday, February 1st: Practitioners' Society of New York (private); Baltimore Clinical Society.

Saturday, February 2d: Clinical Society of the New York Post-graduate Medical School and Hospital; Manhattan Medical and Surgical Society (private), New York; Miller's River, Mass., Medical Society.

Answers to Correspondents:

No. 430.—We have no trustworthy information that Behring's diphtheria antitoxine can be bought in this country at present. We understand, however, that Dr. Paul Gibber, of the New York Pasteur Institute, is prepared to supply the serum obtained by Roux's method. Doubtless an inquiry addressed to that gentleman would elicit more precise information.

Births, Marriages, and Deaths.

Married.

Campbell—Lockheart.—In Ontario, N. Y., on Wednesday, January 9th, Dr. Joseph Campbell, of Ontario, and Miss Rose Lockheart, of Brighton, Canada.

Hayes—Crowley.—In Rochester, N. Y., on Thursday, January 17th, Dr. D. J. Hayes, of Chicago, and Miss Julia Crowley, of Rochester.

Kirwan—Ashbrook.—In Philadelphia, on Tuesday, January 22d, Dr. George H. Kirwan and Miss Maude De Vere Ashbrook.

Died.

Atwood.—In Ferguson, Mo., on Friday, January 11th, the wife of Dr. Le Grand Atwood, in her fifty-ninth year.

Barrows.—In Janesville, Wis., on Monday, January 14th, Dr. Lyman J. Barrows, aged sixty-nine years.

Dummein.—In New Orleans, on Friday, January 18th, Dr. Emile Dummein, in his sixty-first year.

Harpke.—In Milwaukee, on Saturday, January 12th, Dr. Henry Harpke.

Jobse.—In Milwaukee, on Saturday, January 19th, Irvin William, son of Dr. and Mrs. William Jobse, in his sixth year.

Loomis.—In New York, on Wednesday, January 29d, Dr. Alfred Loomis, aged sixty-three years.

Nason.—In Troy, N. Y., on Friday, January 18th, Dr. Henry B. Nason.

Obituaries.

ALFRED L. LOOMIS, M. D., LL. D.

Professor Loomis died at his home, in New York, on Wednesday morning, the 23d inst., as the result of pneumonia of only a few days' duration. Although he was neither feeble nor aged—but just turned sixty-three, of a robust constitution and irreproachable habits—pronounced cardiac weakness was a prominent feature of his illness almost from the very outset of the attack.

Dr. Loomis was born in Bennington, Vermont, on October 16, 1831. After having been graduated from Union College, in 1850, he came to New York and studied medicine with the late Dr. Willard Parker. In 1852 he received his medical degree from the College of Physicians and Surgeons. After serving the regular term of two years on the house staff of the Ward's Island and Blackwell's Island hospitals, he entered upon private practice in New York and devoted himself more particularly to the study of the physical diagnosis of diseases of the chest, a branch of
medicine in which he soon won distinction and eventually unexcelled eminence. It was not at first, however, that he was enabled to teach this department of practice—according to the writer's earliest remembrance of him as a teacher, he was giving clinical lectures on venereal diseases in the Charity Hospital, now known as the City Hospital, on Blackwell's Island. He was subsequently appointed a physician to Bellevue Hospital, and held the appointment up to the time of his death. In 1862 he was appointed lecturer on physiological diagnosis in the College of Physicians and Surgeons. In 1866 he was made adjunct professor of medicine in the Medical Department of the University of the City of New York, and subsequently he was appointed professor. He held the chair of medicine for the rest of his life, and it was in his didactic instruction in the college and his clinical teaching in the wards of Bellevue that he made himself felt in the profession. He was a member of many medical societies and a consulting physician to various hospitals. He was president of the New York Academy of Medicine for two terms at a point in its history when much energy, intensity of purpose, and sagacity were called for to guide it in safety through the perils of financial undertakings that could not have been much extended without crippling it. Well has the present president of the academy, in the inaugural address published in this issue of the Journal, spoken of him as "the sagacious Loomis."

Dr. Loomis was not endowed by Nature with that stately and graceful deportment by which many a physician of mediocrity has attained to a remunerative practice with comparatively slight effort; he really "climbed over the shoulders of the poor into the pockets of the rich," and the process was not a speedy one. The greater portion of his professional career, therefore, was one of hard work and poor pay, but his progress was steadily if slowly upward, and during the later years of his life he was one of the best-patronized consultants in New York. It was his real worth, not the glamour of his personality, that gave him his eminence. His loss is serious to the community, to the profession, and especially to the school of whose faculty he was the shining light. His memory will be fitly perpetuated by the Loomis Laboratory attached to that school.

Letters to the Editor.

TABLES OF INTESTINAL OPERATIONS.

Brooklyn, January 19, 1895.

To the Editor of the New York Medical Journal:

Sir: In your issue of this date is a letter from Dr. F. H. Wiggin, calling attention to the fact that a table appended to an article by the Drs. Mayo in the January number of the Annals of Surgery is practically identical with one published by himself in the New York Medical Journal of December 1st. If this letter has any force it is in the implication that the Drs. Mayo copied Dr. Wiggin's table without giving him any credit for it. While the Drs. Mayo are abundantly able to take care of themselves, I will venture, while the matter is warm, since you have deemed it of importance enough to publish the implied charge, to say that this paper by the Drs. Mayo was received by me from them early in October; that it was in print to appear in the December issue of the Annals of Surgery, but was crowded over until January. It is quite evident, therefore, that its authors in their Minnesota home knew nothing of the New York surgeon's work published in the New York Medical Journal, December 1st. They frankly state in their paper, in so many words, that their table was furnished to them by Dr.

Murphy, of Chicago. It is quite evident that Dr. Wiggin's table is from the same source. The accident of his paper, with Dr. Murphy's table, appearing in print before the paper of the Drs. Mayo, with Dr. Murphy's table, certainly gives him no special property in the table. Kindly give this note a place in the next issue of the New York Medical Journal.

LEWIS S. PILCHER, M. D.,
Editor of the Annals of Surgery.

NEW YORK, January 22, 1895.

To the Editor of the New York Medical Journal:

Sir: As a misunderstanding seems to have arisen about the authorship of the tables of intestinal operations which appeared in connection with my paper on Intestinal Anastomosis, published in the New York Medical Journal of December 1, 1894, I wish to state that the tables were the joint production of Dr. Murphy and myself, and were the result of a correspondence begun in July last. I wrote to Dr. Murphy at that time, telling him that I was preparing this paper, and asking him if he cared to give me any new information regarding his method. In reply he wrote me that he had collected a number of recent cases—some of which had not been reported—which he would send me in September. In the interval I collected a number of cases which had not been published, and in return I sent these to Dr. Murphy. I understood that these cases had not been furnished by Dr. Murphy for publication, or given by him to any one else for that purpose. I had distinctly told him that I did not wish to use them under those circumstances. I was naturally surprised, therefore, when I saw what seemed to be a copy of my table in the January number of the Annals of Surgery. I may add that I gave due credit in my paper to Dr. Murphy for his share in the work.

FREDERICK HOMLE WIGGIN, M. D.

A CASE OF RAPID REPRODUCTION.

ACRE, W. Va., January 5, 1895.

To the Editor of the New York Medical Journal:

Sir: On the 22d of September, 1892, I attended Mrs. A. P. C. in confinement. The child, a female, died on the third day with icterus. On the 20th of January, 1894, I delivered Mrs. C. of quadruplets—four girls, each weighing three pounds and three quarters. The first one born lived an hour, the second lived half an hour, and the two others were stillborn. The great characteristic feature of these quadruplets was their symmetry in development and weights. On January 1, 1895, I attended Mrs. C. again, and delivered her of a living female.

L. M. CAMPBELL, M. D.
they were almost entirely composed infiltrated all the layers of the mucous membrane down to the periosteum. Therefore, when we spoke of the complete removal of adenoid growths from the nasopharynx, and took the expression literally, we meant skinning the entire region down to the bare bone. Of course, very few were prepared to do so radical an operation; furthermore, some very disastrous results had been reported from too free a removal of adenoid tissue.

The cases of recurrence that had come under the speaker's observation he had been disposed to ascribe to imperfect removal in the beginning. As a rule, however, the ordinary operation with the forceps followed by scraping with the finger-nail or some form of curette was sufficient. When an appreciable amount of tissue was left behind, the subsequent irritation and inflammation might be the cause of a recurrence, or it might be the result of a syphilitic or tubercular dysarthria. In other cases a malignant element might be present. A number of cases have come under his observation in which there had been recurrence of tonsillar hypertrophy after removal.

Dr. W. K. Simpson said that Dr. Hopkins' paper had emphasized two very important facts: one was the necessity of completely removing the adenoid vegetations in the nasopharynx, and the other was the difficulty of determining whether this had been done or not. After a certain amount of the tissue had been lacerated, it was not easy to determine with the finger whether any remained. The consensus of opinion regarding this question seemed to be—leaving out of consideration any particular dysarthria—that the recurrence of these growths depended on the fact that they had not been thoroughly removed, certain tags or shreds having been left behind. Very rarely did recurrence take place after a second operation.

Dr. R. C. Myles said that only in a few instances had he seen any recurrence after a thorough removal under anesthesia, and then never to the extent of producing even half the objective or subjective symptoms which had existed before the operation. The development of new lymphoid tissue was going on in some children all the time. In some cases he had seen it grow around the margins, especially at the posterior nares, where it frequently escaped notice. The desirable thing was to find out how much adenoid tissue each child was entitled to.

Dr. Coakley said that in the case of a girl, aged sixteen years, the obstruction in the nasopharynx had been very marked, projecting below the border of the soft palate. This had been removed, and during an examination made a few days later a small tag had been seen near the Eustachian orifice on the left side which had been left undisturbed. Six months later the girl had returned, and quite a good-sized mass had been found where the small tag had previously been located.

Dr. Gleitsmann said he believed in the radical removal of adenoid vegetations; the more radical the operation, the better would be the results obtained. He therefore preferred to operate under anesthesia with the postnasal forceps, and operated with the child in the sitting posture, held by two assistants. In over seven hundred cases he had never had an untoward accident; and of late years he had had fewer recurrences than formerly. It was well in all cases to give a guarded prognosis, and to keep the patient under observation for some months after the operation.

Dr. Walter F. Chappell said he agreed with the previous speakers that the recurrence of adenoid growths in the nasopharynx was extremely rare, and that it was probably the result, usually of incomplete removal. He made it a practice to ascertain, some weeks after the operation, if there was any adenoid tissue left behind, and, if there was, to make an application of silver nitrate.

Dr. F. J. Quinlan said he thoroughly indorsed the statements made as to the rarity of recurrence. In two cases in which recurrence had been more or less marked he had found an obstruction of the anterior nares, and after he had removed this there had been an immediate shrinkage of the adenoid tissue in the nasopharynx. Anterior obstruction, he thought, might often be the causative factor of a recurrence in these cases.

Dr. James E. Newcomb referred to an article recently published in a French journal, in which the writer recommended washing out the nasopharynx with the finger around which a piece of iodine gauze was wrapped; in this way the writer professed to wash off many of these small tags and get a comparatively smooth surface. The speaker agreed with Dr. Quinlan that it was very important, in the treatment of these cases, to inspect the anterior nares thoroughly and remove any obstruction that might be found there.

Dr. J. F. McKeon said that in some instances recurrence of adenoid growths in the nasopharynx was undoubtedly due to an incomplete operation, while in others the cause was yet unexplained. In the cases reported by Dr. Hopkins, some of which he had had the opportunity of witnessing, the operation had been very thoroughly performed. In one instance the operation had been done in two sittings; after as much as possible of the tissue had been removed, the patient had been allowed to recover partially from the effects of ether and the vault had been carefully examined; it had then been swabbed out and all haemorrhage checked before the instrument had been reintroduced. That case had been kept under observation for several weeks, and no tags had been discovered even two months after the operation.

Dr. Bynon Delany said that the partial removal of adenoid vegetations from the vault of the pharynx might possibly in a few exceptional cases result in cure. Experience proved, however, that as a rule the contrary was true. The only safe course was to remove such tissue as carefully and as thoroughly as possible. This course, he thought, could not be advocated too urgently. In cases where so-called recurrence took place, one of two factors was apt to be the cause: first, the removal had been incomplete and large folds of adenoid tissue had been left, which before the operation had been compressed by other masses. The latter having been removed and the pressure thus relieved, the remaining masses had become engorged and had increased in size to such an extent as to re-establish the condition of occlusion which the operation had temporarily overcome. In the second class of cases, rare but not unknown, a persistent tendency to recurrence was often due apparently to the presence of the tubercular diathesis or to inherited syphilis. In such cases, prior to the first operation, a guarded prognosis as to recurrence should be given.

The operation in children was best performed under anesthesia, and sufficient time should be given to it to insure completeness. In most cases the more rapid the operation the less satisfactory was the result likely to be. In his hands the use of some of the most popular of the new instruments for rapid operation had given results far less satisfactory than the forceps applied under anesthesia. He believed that many of the recurrences reported could be traced to this fact.

Nasal stenosis often occurred in connection with adenoid hypertrophy, especially in older children, and it should, of course, be recognized and treated, and the patient not dismissed until all obstruction had been removed as far as possible. The speaker stated that it had been suggested to him that a secondary operation in cases of recurrence would be more likely to be attended with hemorrhage than a primary operation, on account of the division of cicatricial tissue. Personally, he did not agree to this hypothesis.
New Inventions, etc.

A NEW NASAL SPECULUM.

By EDMUND D. SPEAR, M. D.,
AURAL SURGEON TO THE MASSACHUSETTS CHARITABLE EYE AND EAR INFIRMARY.

A properly constructed nasal speculum is of great importance to the medical profession, especially to all whose daily experience with nasal disorders requires frequent examinations of the nose.

The difficulty of seeing the interior of this organ is increased by the use of imperfect instruments, and has been the incentive to the invention of the new nasal speculum here described and figured. Quite a variety of specula are in more or less constant use, but none have been constructed upon mechanical principles which always insures their usefulness, nor are any made with reference to an important anatomical peculiarity of the nose which the writer has taken notice of in constructing his new instrument.

It will assist my explanation to refer to the shape and position of certain parts of the nose, and will aid in the use of the speculum. The ala or wing is situated upon a different plane from the cartilages forming the tip or end of the nose. For this reason it is necessary, in order to adjust the ordinary instrument, to thrust the blades quite deeply into the nose so that the ala shall be lifted out from the nostril and clear vision obtained. The blade of the instrument thus held upon the septum is carried more deeply than it should be, in order that the other blade shall catch inside the ala and not slip.

In this new speculum the movable joint permits a crossing of the handles and an advance of one blade beyond its fellow (side cut, a a), so that when the septum has been reached the ala can be held outward without the necessity of thrusting the blades of the instrument deeply into the nostril where the bony opening forms an undilatable passage. One of the blades is flattened, to be placed against the flat septum. By inverting the speculum when examining the left side this blade will likewise be brought against the septum.

The writer is indebted to Messrs. Tiemann & Co., of New York city, whose unqualified workmanship and valuable suggestions have enabled him to obtain such perfection in its construction.

A NEW INTRA-UTERINE IRRIGATOR, DILATOR, AND RÉCAMIER CURETTE COMBINED.

By HARRIS B. ADLER, M. D.

During many years of an active gynecological and obstetrical practice I have frequently met with cases of adherent or retained placental tissue where curetting and irrigating the uterus were necessary, and I have always found it difficult to obtain an instrument which possessed the combined qualities of effecting sufficient dilatation and irrigation of the cavity. I have, therefore, been led to devise an instrument which is simple in design and perfectly aseptic.

The subjoined cut shows the instrument both closed and partly open. It is capable of carrying a stream sufficiently large to wash away detritus to an extent not attained by any instrument heretofore in the hands of the profession. Fig. 2, a, is practically a straight cannula, through which a rod an eighth of an inch in diameter can easily be passed for cleansing purposes; or a piece of sponge, attached to a wire supplied with an eyelet, can be drawn through, and the instrument kept clean and perfectly aseptic.

The instrument is as easily manipulated as any ordinary uterine dilator, and, when it is introduced into the uterine cavity and opened to its fullest extent, by gentle traction the uterus can be brought down without the use of a tenaculum. The instrument consists of two parts, the injector and a Récamier curette, held together by a modified French lock, b, the blades being kept closed to form the dilator by means of an adjustable spring.

Thanks are due to Messrs. Tiemann & Co. for the careful and skillful manner in which they have constructed the instrument, and it is hoped that it will prove useful in the hands of obstetricians and gynecologists.

212 East Broadway.

Miscellany.

Corporal Punishment for Certain Forms of Crime.—At a meeting held in the Academy of Medicine's building on Wednesday evening, the 9th inst., under the auspices of the Section in Hygiene, Dr. Andrew F. Currier read a communication of which the following is the substance:

I appeal to the medical profession that it lose not the opportunity of co-operating in this movement, and I know not how its interest can be better shown than by pleading for the enactment of a law which shall secure or tend to secure a measure of justice for a class of sufferers with which it is all too familiar. If any treatment of the subject more equitable than the one which is to be proposed shall suggest itself to any one here present, it is earnestly hoped that it will be advocated fearlessly. All that is asked is that something positive be offered by those who find themselves unable to agree with the recommendations which are to be made; destructive criticism alone will not help those for whom help is sought.

Laws have been enacted and are enforced for the prevention of cruelty to animals, wise and watchful eyes are solicitudes in preventing cruelty to children, why should women look in vain for that protection from brutes and ruffians which we do not deny to animals? [The author then cited a number of newspaper accounts of cases of gross cruelty to women, and continued as follows:]

These cases have not been picked out after an extensive search in the newspapers for such material. They are simply instances that have come under my eye within the past few weeks in the course of the daily reading of the newspapers. We will take them as the basis of our argument as to whether women of this particular class or with this particular experience need protection. But it may be objected that these stories were
all taken from the newspapers and were varnished for effect. The reply to this would be that we have here a class of cases in which hyperbole is impossible, and I am prepared to vouch for almost equally revolting experiences which have come within my own observation. [Dr. Currier then briefly narrated a number of examples in which he had been personally cognizant of the facts, and continued thus:]

These experiences, so revolting to the feelings and the imagination, are narrated not because they are singular or unique, for many who are present could parallel them in their own observations, but because of the enormity of the offenses, the futility of present means of punishment, and the earnest desire to find a remedy. We know that many of the victims of this inhuman treatment suffer in patience and in silence, not knowing where to look for protection and justice, and doubly many of them die with their wrongs unrepressed. Many others continue to keep alive the divine spark of love and consideration for those who should be their protectors and are unwilling to have them suffer punishment. Unfortunately, too, it often happens that political considerations prevent a magistrate from dealing as sternly with this class of offenders as the occasion may warrant; a ward heeler who has been severely punished by a judge is not apt to forget it when the next election takes place and the judge or his friends are running for office. But, assuming that the judge administers the law fearlessly and conscientiously, if a felony is not proved, the most that he can do is to reprimand the prisoner and inflict a fine or a short imprisonment upon the island. What does the average man who is scoundrel enough to beat a woman care for such penalties? The reprimand does not give him any pain; the fine is often paid by the wife, and in any case comes from the slender income of the family; the imprisonment means comfortable quarters, plenty of food, and healthful work. The imprisonment ended, the man goes back to his home and his old companionship; he is not reformed, and takes the first opportunity to "get even" with his wife for having had him arrested. To a nature thus depraved there is but one effective appeal in the way of punishment that I can conceive of, and that is something which will give him physical pain. A man who has once felt the sting of pain will understand the sensations which are experienced by a beaten woman. One who has had a severe dose of such medicine will not conduct himself, as a rule, in such a way as to invite a repetition of it. The objection to such a mode of treatment which meets us at the outset is that it is degrading and barbarous, a step backward, and a return to the measures and methods of a society less highly civilized than our own. We may be highly civilized, but the events of the past few months teach us that if we scrape away a very thin crust we find a social condition which is not very flattering to our pride, and that our civilization may have been developed along lines which it would be quite desirable to retrace.

I do not believe that corporal punishment can degrade to a lower depth one who is so deficient in manliness as to strike and pound one who is physically incapable of self-defense, who forgets the consideration which any decent man should always show to a woman, or who becomes the mortal enemy of his wife, his mother, or his sister, instead of her friend and protector. Certainly such punishment can not be more degrading than the so-called glove contests which are witnessed so approvingly in many of the fashionable clubs of this country.

The object of such punishment being deterrent and reformatory, it is unnecessary to say that it should not be done publicly; the only spectators should be the officer of the law who inflicts the punishment and a physician of known capacity and integrity, who should be a safeguard against any cruelty or undue severity. The infliction of such a penalty could not be a more repulsive duty to an officer of the law than to shackle and fetter a prisoner, or than any of the more violent measures which are at present exercised upon refractory criminals. It is doubtless unpleasant to most men to deprive a fellow-being of his liberty; it should be unpleasant to administer punishment in any form; but as long as men continue to do what the public conscience, which voices itself in the terms of the law, regards as wrong, there will continue to be penalties for such misconduct, and a part of the machinery of justice will consist in administering the penalties therefor. The degrading influence of such a duty will depend partly upon the disposition or temperament of the officer and partly upon the surroundings and scene of the punishment. A judge in a criminal court is not necessarily degraded though he pronounces the severest penalties upon his fellow-men year in and year out. A surgeon is not degraded though he inflicts the severest pain, day after day, upon those whom he seeks to relieve and help. It is equally possible that an agent of the law should inflict corporal punishment upon those who have been adjudged worthy of it without detriment to his moral nature; or, as an additional safeguard, the punishment may be inflicted with predetermined accuracy by means of a suitably constructed machine. The very notion that such a punishment is possible may be sufficient to deter many a brutal man from the risk of sustaining it, while others who have once tried it may hesitate before inviting it a second time.

If it is decided by the Legislature of the State that this form of punishment is proper and advisable, let it be surrounded, by all means, with every possible safeguard to prevent its abuse. Let us insist upon such magistrates to enforce the law as are wise and humane, just alike to the victims of cruelty and to those who have inflicted it. Let there be no suspicion of cruelty or torture in the punishment, but let it be so stern and severe that the criminal will not be willing to encounter it a second time. Let there be no spectacle for sensational accounts in the newspapers, and no spectators but the officer of the law and the physician, who shall be the guaranty to the public that no unnecessary harm shall come to the criminal.

I have endeavored to discuss calmly and dispassionately the question whether the proposition to inflict corporal punishment was a reasonable one at this time and at this stage in the world's history, whether if a law permitting such punishment were enacted it would redound to the benefit of society, or whether it would signify a return to a state in which human life and liberty and happiness would be less secure than they are at present. Certainly those who are the greatest sufferers in the present state of affairs could not be made worse by the proposed law than they are now, and the chances are decidedly in favor of an improvement in their condition by its deterrent action. The fact must never be lost to view that the law is not intended for innocent men, but for those who are universally admitted to be brutal and degraded. As long as codes of law are necessary for social and individual protection, penalties and pain can not be eliminated from them. Let us hear the testimony upon this subject of an eminent English jurist, Sir James Stephen. In his History of the Criminal Law in England (1883) he states (vol. ii, p. 91): "In my opinion the importance of the moral side of the punishment, the importance, that is, of the expression which it gives to a proper hostility to criminals, has of late years been much underestimated. The extreme severity of the old law has been succeeded by a sentiment which appears to me to be based upon the notion that the passions of hatred and vengeance are in themselves wrong, and that therefore revenge should be eliminated from law as simply bad. It is useless to argue upon questions of sentiment. All that any one can do is to avert the sentiment which he holds and denounce that which
he dislikes. I have explained my own views. Those which commonly prevail upon the subject appear to me to be based upon a conception of human life which refuses to believe that there are in the world many bad men who are the natural enemies of inoffensive men, just as beasts of prey are the enemies of all men. My own experience is that there are in the world a considerable number of very wicked people, disposed when opportunity offers to get what they want by force or fraud with complete indifference to the interests of others and in ways which are inconsistent with the existence of civilized society. Such persons ought, I think, in extreme cases, to be destroyed.

From this extreme view I most emphatically dissent, as I do not believe in the principle of capital punishment. It must be admitted, however, that the history of our prisons and reformatories has shown some examples of complete incorrigibility according to all existing methods of treatment.

Resuming the quotation from Stephen: "The view which I take of the subject would involve the increased use of physical pain, by flogging or otherwise, by way of a secondary punishment. It should, I think, be capable of being employed at the discretion of the judge in all cases in which the offense involves cruelty in the way of inflicting pain, or in which the offender's motive is lust. In each of these cases the infliction of pain is what Bentham calls characteristic punishment. The man who cruelly inflicts pain on another is made to feel what it is like. It seems absurd that if a man attempting to ravish a woman squeezes her throat to prevent her from crying out he should be liable to be flogged, but that he should not be liable to be flogged if he puts one hand over her mouth and with the other beats her about the head with a heavy stone."

Concerning the efficacy of corporal punishment in the State of Delaware, we are fortunate in having with us an eminent legal gentleman from that State who will tell us about it from practical observation of its workings. The use of this method of punishment at the Elmira Reformatory has recently been subjected to the most searching investigation and criticism. This investigation and the complete vindication of Mr. Brockway show us that it is possible to use such a method of punishment without abuse. In this connection I beg leave to read the following communication from Dr. W. C. Wey, president of the board of managers of the Elmira Reformatory:

"The question of dealing with misdemeanants of a certain class is perplexing, uncertain, and disappointing, in respect to the results which are looked for in connection with the operations of the law upon them. The periodical or the confirmed drunkard whose occasional outbursts of excitement and temper lead him to the commission of an offense against the law has as little dread of thirty or sixty days in the penitentiary as of missing a meal. In some cases it is understood that offenses are committed for the purpose of obtaining temporary asylum in a place of imprisonment. This is particularly noticeable when the confinement does not subject the individual to manual labor or employment of any kind. Subsistence in a jail upon as good food as that procured outside, if not better, with congenial companionship and indulgence in tobacco to an unlimited extent, and without thought of the future, is regarded by many of the men under consideration, not as a hardship, but as an actual privilege—as something to be sought and not avoided. The wife-beater, whose impulse to commit the act is commonly inspired by alcoholics, belongs to this list of lawless characters. He is apt to be a repeater, and prone guilty to intoxication rather than to the more serious charge of assaulting his wife, because of a sentiment in the community which regards drunkenness as a minor offense, while the maltreatment of a woman is looked upon with chivalrous indignation.

"Taking this case as an illustration of the methods in operation under the law by which so-called punishment is meted out to an offender, the question is at once suggested if it does not fail of its purpose—first, to inflict suitable pains and penalties; next, to prove deterrent in its influence on others who may be like-minded as transgressors; and again, if it affords protection to such as are chiefly involved as sufferers in the aggressions which belong to our one-sided social state. That it fails of its purpose to impress offenders sufficiently to turn them from habits which are begotten of gross license and demoralization is apparent; that it is not preventive, in them or in others, of endless varieties of brutal acts is equally plain, and that society and individuals continue to bear the burdens which grow out of such displays of human passion, without adequate remedy, will not be gainsaid.

"In the treatment of such offenders I am convinced that corporal punishment will afford relief to outraged public sentiment, in connection with their acts, and to the forbearing victims of wife-beating, for instance, which a money penalty or a short period of imprisonment has failed to accomplish. Under judicious supervision and execution such a mode of punishment can be conducted in a way to be consistent with the dictates of humanity and insure the best results to men thus subjected to physical treatment.

"The following extract is made from the recent Flint-Deyo report of the investigation of charges against the management of the New York State Reformatory: 'During the five years immediately preceding September 30, 1893, when the use of corporal punishment in the reformatory was suspended, three hundred and seventy-three inmates were reported for fighting, an average of 37.3 for each period of six months during that time. During the six months immediately following the suspension of corporal punishment, a hundred and seventy-two inmates were reported for the same offense, or more than four and a half times as many of the average number reported for that offense during any corresponding period of six months within the five preceding years.'

"The minor world of the reformatory is but a reflex of the greater world outside, and it is reasonable to assume that fear of personal contact with the representatives of violated law will prove more deterrent to men fastened to the whipping post and to others inclined to evil ways than the usual methods of punishment at the present time in force.

"A distinguished professor in one of the leading American colleges, a few months since, in the presence of his class, spoke so approvingly of the purpose and results of physical treatment in the reformatory that he was asked by a student if he would sanction such a practice with him or his fellows, in case of positive delinquency of duty, to which he replied, with earnestness, 'Yes, indeed, if your shortcomings were not followed by expulsion.'

"At any rate, the experiment should have full opportunity of being submitted to the public to determine its efficiency. It is short, sharp, and decisive in its operation. Its physical effect is evident, its moral power is unquestioned. In the State of Delaware it has had such a successful history and for so long a time as to be established in the confidence of the best citizens of that commonwealth.'

Now if we are willing to admit that corporal punishment is ever justifiable for insubordination and for certain misdemeanors incidental to the discipline of a prison or reformatory, and if we accept the statements concerning the beneficial results which have attended its employment at the Elmira Reformatory—and it must be conceded that the testimony of those who have made a careful study of this phase of the subject in the foremost institutions of the world and have had nothing but praise for the work of the Elmira Reformatory is worthy.
of greater credence and regard than the opinions of those who argue merely upon the ground of sentiment—much more are we bound to admit that such punishment is justifiable for cruelty and felonious assault upon the persons of women. For myself, I believe that any man who strikes a woman, if it be but a single blow, should be soundly thrashed, and I can scarcely conceive of any one with the instincts of common humanity who would not feel impelled to do the thrashing, if he was able, if the cowardly blow was struck in his presence, but if the victim was a wife, sister, daughter, or aged mother of the guilty person, whom natural instincts would impel to defend and not maltreat, if, moreover, the victim was knocked down, dragged about by the hair, thrown down-stairs, kicked, unmasked, or disfigured in any way, beaten with a club, or attacked with a knife or axe, all of which cowardly acts are repeatedly done in this community, my charity does not reach the limit of letting off such a brute with fine and imprisonment. A hard whipping inflicted upon such a person would do him good, and the whipping should be repeated with increasing severity if the offense was repeated.

I have already referred to the safeguards which should be thrown around such punishment, its object being serious, remedial, deterrent, and not revengeful, justice to the criminal and a means of protection and defense to his victim.

There is little fear that such an offender will receive serious injury from the punishment which has been advocated. One who is vigorous enough to beat a woman is usually sufficiently vigorous to endure the penalty of his crime.

With regard to the portion of the body upon which the punishment should be laid, while I have not considered the matter in all its bearings and may change my opinion, my present view is, from such thought as I have given the subject, that the method of spanning upon the bared buttocks, more or less similar to the method in use at Elnehira, is least open to objection, is far preferable to the use of a whip, and is far less likely to be abused than any method with which I am acquainted.

All other portions of the body can remain covered, none of the important organs can by any possibility be injured, while the smart and sting of a punishment upon the buttocks can be made sufficiently acute to furnish a profound impression. The disgrace of such a punishment to the offender is hardly worthy of serious consideration; he has already sounded the depths of degradation.

In conclusion, if the measures which have been advocated should command themselves to the members of the profession in this city, I would recommend that a petition signed by those who are in sympathy with this movement be sent to the Medical Society of the State of New York at its meeting in February, urging the appointment of a committee to draft a suitable bill, and that the same be presented to the Legislature during the present session for enactment into law.

Mr. Elbridge T. Gerry delivered an address in which he said:

When those who are deeply interested in the welfare of little children can in addition enlist the powerful, active, pronounced aid of the medical profession in support of their efforts, the task of satisfying the Legislature at Albany of the propriety of changes in the law is comparatively an easy one. The medical profession have a weight and influence with the Legislature of which they are but little aware. The suggestions of the family physician are heeded when political arguments are of no avail; and, however the learned members of your profession may disagree, one thing is very certain, and that is that when they do agree their conclusions have a weight with the community not easily overthrown or laid aside. I have more than once experienced this in the efforts made by the society which I represent to protect helpless childhood. Its arguments are never so strong as when enforced by clear, held statements of the effects of injuries, from the lips of medical men, whose familiarity with pain and suffering enables them to plead the cause of helpless childhood more effectively than any mere words of eloquence or any form of abstract propositions. It rests with you tonight to determine whether what I shall propose merits your approval. If it does, you will accomplish a radical change in the punishment of criminals which will be calculated to produce results in the life of deterrent effects beyond what you can even remotely suspect. Now let me turn to my subject.

The infliction of corporal punishment for breach of the law is one of the oldest methods known to antiquity, and has the direct sanction of the Mosaic law. Thus, in eastern countries the application of the bastinado still survives as a consequence of the imposition of the "forty stripes save one" which Moses enjoined, even for minor offenses. It is intensified in Russia by the application of the knout until its effects become lethal in their result. It possesses the advantage that it does not require skill or talent in its infliction. When it is inflicted under the advice and in the presence of a medical man, dangerous consequences can not be expected. It is, therefore, neither a cruel nor an unusual punishment, which is the subject of Constitutional prohibition. (Footnote, The State, 59 Maryland, R. 294.)

Then the sole question which remains for the Legislature to determine is as to the propriety of its infliction in the cases to which I shall invite your attention.

There are a certain class of felonies punishable at the present time by imprisonment in the State prison, which consist in or are accompanied by the infliction of physical pain and suffering by the perpetrator upon the victim. Familiar illustrations of the first are cases of highway robbery, when an unoffending citizen is felled by a blow from the butt of a pistol or a loaded club, resulting possibly in a fracture of the skull or a broken limb, or certainly in severe contusions. Another illustration is that where in a quarrel a deadly weapon is used, constituting a felonious assault, or, as it is termed in the Penal Code, an assault in the second degree, which may possibly enlarge the offense to murder, and where the nature of the offense is to inflict grievous bodily harm upon the victim. Yet another illustration is that of ordinary rape, where a female is deprived of her chastity after the utmost reluctance and resistance, and irreparable injury is inflicted upon her chariater as well as her person, never wholly to be effaced during the rest of her earthly life. And, last but not least, is the commission of similar acts, including those against the course of Nature, upon the persons of very young children, where the victims are absolutely powerless and at the mercy of their brute assailants, where physical lacerations of the most frightful character are the result, and where in some States other than our own lynch law is unhesitatingly resorted to as the only proper punishment for the offender. The great object of the criminal law is not simply to punish the offender for the crime, but, as the old law books have it, to deter other evil-minded persons similarly disposed from in like manner offending. It is to this end that, according to the magnitude of the crime, the sentence is made correspondingly more or less severe. Where life is taken by the offender wilfully and deliberately, unless justified or excused, the act involves the loss of his own life. In all other cases the punishment consists in the infliction either of a fine or of imprisonment, the length of the term depending upon the magnitude of the offense. In prison the offender leads a routine life. He performs a certain amount of exacted work; he is fed on simple but unwholesome food; his physical condition is carefully looked after by competent medical men; his clothing is supplied at the expense of the State, which practi

one, and others, while conceding that it might be proper in the case of grave offenses, thought it would tend rather to encourage brutality by the creation of vindictive feelings on the part of the offender on whom it was inflicted. It is for this reason that in the present bill the limitation, as you will observe, is to cases of felony. Should it succeed in obtaining, as it is believed it will, the sanction of the Legislature, and should it prove efficacious in these cases, it will be very easy to extend it to minor offenses; but, if the reverse course is tried, it is much to be feared that the former prejudices which operated in 1881 will be revived to the detriment of the whole measure.

Now, another objection to the bill is that it is the relic of a by-gone age, in view of the fact that it originated with Moses; and that our advanced civilization requires that more humane methods should be resorted to for the prevention and punishment of crime. The answer to this is a perfectly simple one. The method which is the most efficacious and the simplest is always the most desirable in cases of this sort, because the object of the law is not simply to punish crime, but to deter persons from committing crime. It is a question of political economy, because after the crime is committed, in case of imprisonment, the State is bound to support the offender, whereas, if the crime is prevented, the State is relieved from the necessity and expense of so doing. From a practical point of view, therefore, whatever tends to diminish crime tends to diminish the expenses of the State; and it is this view which will be urged before the Legislature as a strong argument for the adoption of this measure.

The last objection is that corporal punishment is brutalizing, that it tends to degrade the individual upon whom it is inflicted and to destroy his self-respect. The answer to this is equally simple. Those who suggest such an idea should be called upon to define what possible self-respect can exist, even in the remotest degree, in him who commits an atrocious crime of rape or sodomy upon a helpless little child. Surely if the dread of physical punishment legally inflicted, with proper precautions against dangerous results, will operate in the slightest degree to prevent the continual spread and increase of these frightful crimes against infancy, there should not be the slightest hesitation on the part of any humane man in not only indorsing but advocating such a measure, in the interest of our common humanity, and for the protection of his own little ones, who, in an unguarded moment when absent from his personal care and protection, may be the next victims of brutal lust, because with such wretches as those who perpetrate these crimes only one thing is needed besides the victim, and that is the opportunity.

It is, then, to the medical profession, in the presence of whose representatives under the provisions of this law the punishment is to be inflicted, that the Legislature shall so decree, that the Society for the Prevention of Cruelty to Children now addresses this appeal, in the earnest hope that they will give it that hearty support and co-operation which are most certain to insure its final passage in the Legislature, and thus illustrate what has long been an axiom of their profession, that an ounce of prevention is worth a pound of cure.

The Discovery of Anæsthesia.—Dr. William J. Morton, the son of Dr. William T. G. Morton, has furnished us with certain memoranda relating to the discovery of anaesthesia. The most interesting of these documents seems to us to be the following letter, a portion of which was recently published in the Century Magazine:

"Boston, April 2, 1823.

"My Dear Sir: Few persons have or had better reason than myself to assert the claim of Dr. Morton to the introduc-

The Medical Society of the State of New York will hold its eighty-ninth annual meeting in Albany, on February 6th, 7th, and 8th, under the presidency of Dr. George Henry Fox, of New York. The programme includes the following papers: Clinical Notes on Psoriasis, with Special Reference to its Prognosis and Treatment, by Dr. L. Duncan Bulkley, of New York; Shall Insane Criminals be Imprisoned or Put to Death? by Dr. J. B. Rawson, of Dannemora; The Brain of a Suicide with Two Pistol-shot Wounds, by Dr. Burt G. Wilder, of Pittsfield; The Surgical Treatment of Empyema of the Aurum of Highmore, by Dr. Samuel Lloyd, of New York; The Use and Abuse of the Animal Extracts, by Dr. Henry W. Post, of Fultonville; A Few Experiences with Diptheria Antitoxine, by Dr. Nelson G. Richmond, of Fredonia; The Treatment of Væperal Fever Septicaemia by the Country Practitioner, by Dr. John Mann, of Jericho; Ringed Eruptions: A Study in Differential Diagnosis, Illus-
Observations on the Medical Department of the British Army by an Officer of the United States Medical Service.—We lately reprinted an article on Colonel Woodhull's report from the British Medical Journal. We now reproduce the following from the Lancet for January 12th:

"We recently very briefly adverted to Brevet Lieutenant-Colonel Woodhull's Observations on the British Medical Service, abridged from an official report and published by authority of the Secretary of War of the United States. These observations are reprinted from the fourth volume of the Transactions of the Association of Military Surgeons of the United States. The writer of this abridged report is a distinguished officer of the American medical service, and he is certainly to be congratulated on the ability and accuracy with which he has discharged the duty committed to him. While in England, in 1891, he was ordered by the War Department of the United States to make the utmost use of such facilities as might be granted to study the British military hospitals, the army medical school, the duties of medical officers, the sanitary administration of barracks and camps, the instruction service of the Medical Staff Corps, and the system of physical training in the British army. It will be seen that the scope of his inquiries was sufficiently comprehensive, and he has evidently been indefatigable in his efforts to obtain a good firm grasp of his subject. The results are embodied in the abridged report before us. It is surprising what an amount of well-arranged information Colonel Woodhull has managed to incorporate in a condensed form in this report, which should, and probably will, be extensively read by medical officers of the British service. Sydney Smith humorously traced how taxation shadowed every step and stage in the career of a British subject, and Colonel Woodhull has, it may be said, in a similar manner traced the British soldier from the cradle to the grave; he has described and analyzed our army medical regulations, our service customs and practices, as contrasted with those of his own service, and in a running commentary frankly reviewed our methods in an honest, independent spirit, but always in excellent taste.

"From what we have said it will be seen that it is impossible, nor indeed is it necessary, to accompany Colonel Woodhull through all his inquiries and comments; we can only attempt to select a few points. Passing over his general remarks on the strength and organization of the British medical department, the entrance examination and the course at Netley, and the system of promotion in the various grades and the duties assigned to each of them, he points out, en passant, some minor practical differences between the medical service of this country and that of the United States, and adverts to the subject of the roll of married soldiers in the British army, which, judged by any ordinary measure of a combatant force, is, he says, enormous and draws deeply on the medical as well as on the other sources of the establishment. Much consideration is given to the subject of diets in British and American army hospitals and the different systems on which these are based respectively. The diet of the United States hospitals is, it may be mentioned, very liberal and varied, and it is so different from that of our army that no useful comparison can well be made. Speaking of medical history sheets—which we regard as excellent and most useful documents in our service, with its soldiers serving in all parts of the world—Colonel Woodhull does not, on the whole, and for the reasons he gives, think that their adoption in the American service would be attended with any great advantage. As regards the nursing sisters of our service, he says that he formed a very favorable impression of this trained section of the nursing staff. Alluding to the functions and authority of the director general, he remarks that these greatly transcend those of the surgeon.
MISCELLANY.

By restraining promotion in the lower and medium grades to seniority, moderate ambition and moderate abilities are satisfied; and opening the higher ranks to choice presents a stimulus for exertion, and relieves the administrative positions from the inertia and indifference that sometimes accompany age. Colonel Woodhull has a good deal to say about recruiting, and particularly about the Medical Staff Corps. Like anybody else who has any practical knowledge of the subject, he is opposed to the limitations of stature now in force for the men of this corps, uniting them as they do for the work they will have to perform in war. His comments on the Aldershot system of training of the Medical Staff Corps are very favorable, although he considers that in several particulars the methods pursued in the United States service are simpler and better adapted to the general end in view, and therefore to be preferred. In connection with this subject we may say that Colonel Woodhull expresses his surprise that the Army Medical Service and Medical Staff Corps are not more practically utilized at our autumn manoeuvres than they are.

Colonel Woodhull also considers that his army service has nothing to acquire from Great Britain in the system of tentage, whether considered for shelter, artificial warmth, convenience of transport, or adaptability to campaigning purposes. Speaking of our barrack rooms, he thinks that the men can hardly be warm enough for comfort, and this is a matter in which they would certainly agree with him, for the insufficient allowance of fuel and the draughty nature of these rooms in cold weather are common complaints with soldiers.

"Referring to the subject of medical and sanitary instructions for field service, we are glad to notice that he gives some extracts from those issued in this country for the Suakin Expedition, which he very highly commends for their scope, intrinsic value, and general usefulness, expressing at the same time his regret that he failed to note the name of the officer who prepared these valuable memoranda. We may here incidentally remark that the Lancet drew special attention to the excellence of these instructions at the time they were issued. Colonel Woodhull devotes much consideration to Netley and to the value of such an institution to the State and the army. Although the courses at Netley and Aldershot overlap in some respects, he holds that, taken as a whole, 'they are both admirable, and are strongly commended for our imitation.'

"With reference to the various forms of transport for wounded he saw nothing as regards comfort and economy of force and the requirements of the American army to approach the train and the Dally litter.

"Colonel Woodhull's remarks on gymnasia and the physical training of the British soldier strike us as pertinent and good. The physical development of the soldier, in whom the fighting instinct is naturally strong, gives to the British army, he says, much of the formidableness it possesses, notwithstanding certain deficiencies in the original material and other incidental conditions of the service.

"But here we must stop, contenting ourselves with hoping that we have said enough to show that the report under review is both interesting and instructive, and consequently well worth reading."

Sanitary Climatology.—This is the title of a circular recently issued by the Weather Bureau of the Department of Agriculture. The circular reads substantially as follows:

The interest manifested by every class of people in the subject of climate and its influence on health and disease has determined the Honorable the Secretary of Agriculture, through the medium of the Weather Bureau, to undertake the systematic investigation of the subject. It is hoped to make the proposed investigation of interest and value to all, but especially to the medical and sanitary professions and to the large number of persons who seek, by visiting health resorts and seeking a change of climate, either to restore health or prolong lives incurably affected or to ward off threatened disease. The study of the climates of the country in connection with the indigenous diseases should be of material service to every community, in showing to what degree local climatic peculiarities may favor or combat the development of the different diseases and by suggesting in many instances supplementary sanitary precautions, also by indicating to what parts of the country invalids and health-seekers may be sent to find climatic surroundings best adapted to the alleviation or cure of their particular cases. The hearty cooperation of the various boards of health, of public sanitary authorities, of sanitary associations and societies, and of physicians who may feel an interest in the work is asked to achieve and perfect the aims of this investigation.

No compensation can be offered for this co-operation other than to send, free of cost, the publications of the bureau bearing upon climatology and its relation to health and disease to all those who assist in the work. Co-operation will consist in sending to the office reports of vital statistics from the various localities. That these reports may be of value, it is evident that they should be accurate and complete and be rendered promptly and regularly. Blank forms of reports have been prepared so as to occasion little trouble and labor as possible on the part of the reporter, and will be furnished by the bureau on application. At the very beginning of the investigation it is not possible to outline precisely the channels through which the results obtained will be made public, but it is hoped to publish soon a periodical devoted to climatology and its relations to health and disease. The publication will probably resemble in size and general appearance the present Monthly Weather Review, the subject matter being, of course, different. More detailed information will be furnished on application to Mark W. Harrington, chief of the bureau, Washington, D. C.

A Triumph of Orificial Surgery.—An orificial surgeon reports in a recent number of a medical journal a case of "philitis" cured by the operation for laceration of the cervix. The patient had a severe and long-continued cough and hectic fever, and what the surgeon calls an "interstitial inflammation of the lungs," with infiltration and obstruction of the air cells. "On the day of the operation the temperature reached 97°, and never rose above 99° afterward." Some light is thrown upon the nature of the case by the surgeon's stating that it was a case of phthisis of neural origin, and that such cases are often successfully treated by "removing the distal point of patholgy." Other successful results of "orificial surgery" are a case in which chronic eczema of the hands was cured by stretching the rectum, and another case of the same disease cured by loosening the "hood" of the ectoris and "clipping of irritated points at the various outlets of the body." Of course, all the resources of therapeutic art had been exhausted upon these cases before they came under the care of the "orificial surgeon." A more transparent form of quackery than some of this orificial surgery can hardly be imagined. The author of the article referred to above states that in his observation "many cases of insanity are made worse by the operative procedure, but the secondary effect is most satisfactory." In his opinion, "a conservative orificial surgeon should be connected with each of our State hospitals for the insane." This last idea seems an excellent one. If he be connected in the proper capacity—that is, as a patient rather than as a surgeon.—Boston Medical and Surgical Journal.
NON-TUBERCULOUS DISEASES OF JOINTS. *

By ARTHUR J. GILLETTE, M. D.,
Minneapolis, Minn.

Such a large proportion of diseased joints are tuberculous, and so many authors give such a large percentage as being tuberculous, that I wonder if we are not often inclined to give a diagnosis of tuberculosis as "to be on the safe side." Our inability to follow up our cases, and lack of opportunity to prove our diagnosis by post-mortem or microscopy, no doubt has tended to lead us into this error.

But there are a number of diseases manifested in or about the joint so often resembling tuberculosis that it is quite difficult to distinguish them, yet the pathology and treatment differ so widely that to treat them scientifically they must be differentiated. To enumerate a few of them—rheumatic arthritis, gonorrheal arthritis, septic joints, Charcot's disease of the joints, typhoid joints, rheumatic joints, epiphysitis, neuritic or hysterical joints, haemophilic, loose bodies in joints, bursitis, synovial hernia, traumatic joints, incised wounds of joints, simple synovitis with effusion, dry synovitis, suppurative synovitis, goyous joints, tumors of joints, syphilitic joints, seborrheic joints, etc.

This list suggested to me the idea of this paper.

It would seem impossible to confuse them from a pathological standpoint; it is, however, the clinical aspect of the case which I wish to present.

Rheumatic arthritis is a disease of the joints characterized by chronic inflammatory and degenerative changes involving the structure of the various articulations and resulting in rigidity and deformity. Of course, our assistance in distinguishing this is in the history and multiplicity of joints involved; but who knows better than the general practitioner how little dependence can be placed on the histories given, and we sometimes find more than one joint involved in tuberculosis, though, happily for the patient, this does not often occur. A woman in middle life was treated in the City and County Hospital for articular rheumatism. She had the best of care. All the joints, save the right knee, were, so far as I could judge, entirely cured, yet some months later she returned to the hospital with a partial laxation of the knee, atrophy of the thigh and calf, enlargement of the knee, and the normal contour of the joint lost. How could I have distinguished this from a tuberculous joint had I not personally known the history, remembering that in most cases of tuberculous joints if the patients have not been treated for rheumatism, they believe this their trouble and give you a history accordingly?

During the past year a man was referred to me. Tuberculous disease of the knee was suspected, and with good reasons: there was atrophy of calf and thigh and the chronic condition of inflammation about the knee. I was about to concur in the opinion of his physician when, by the merest chance, I asked him if he had ever had gonorrhoea. He stated that he then had a discharge from the urethra. After the limb had been immobilized and the urethritis relieved the joint resumed its normal functions and appearance. While preparing this article I was consulted in a case with the following history:

A young woman of the middle class, about sixteen years of age, some three months previous to my seeing her began to have a limp and some pain in the knee. As her general health seemed much below par her physician advised her to go to the country. While there, the pain in the knee increased to such an extent that she was obliged to keep her bed. Blisters, hot fomentations, and liniments were applied, but the pain increased, and she was finally brought back to the city and a physician again consulted. He treated her for a few days, trying to control the pain with morphine. When I visited her it was impossible to move the bed or bedclothes without causing excruciating pain. I naturally examined the knee, from which most of the skin had been removed by the various counter-irritants. Satisfying myself that there was no disease there, I examined the hip joint, and elicited all of the symptoms of tuberculous hip-joint disease, both as to history and appearance. We applied a weight and pulley and left the patient quite comfortable. My diagnosis was tuberculous hip-joint disease, and I am sure I never felt more confident of a diagnosis in my life. A few days later the family physician was taken into the confidence of a certain young drug clerk, who felt we had been groping our way long enough, and that we ought to know that he too was treating the patient and for gonorrhoea, his treatment beginning before the hip trouble developed. From subsequent events and the above-mentioned fact, I believe that the hip trouble was undoubtedly gonorrhoea.

Septic joints come under the same head. They may come from long continued suppuration in any portion of the body; they resemble, and in fact can not easily be distinguished from, tuberculous joints, for it is well known that tuberculous joints often follow closely in the wake of exhausting diseases. Any septic micro-organisms which have gained entrance into the body might readily and often do implant themselves in a joint, occurring without any history of local injury.

It has been long known that Charcot's disease of the joints is sometimes with difficulty distinguished from other joint disease; in fact, can only be distinguished by establishing a positive diagnosis of tabes dorsalis. This certainty is very difficult, especially in the early stage, and by the lack of spasm of the muscles about the joint, which spasm is often lacking in the very early stage of tuberculous disease of the joint. In one of the leading hospitals of the east one of these joints was excised under the supposition that it was tuberculous.

Of late a great deal has been written upon typhoid joint diseases and typhoid spine, a condition following typhoid fever, characterized by acute pains upon the slightest movement and the absence of any marked febrile disturbance, which have been known to go on to suppuration and death, and the only bacilli found was the supposed bacillus of typhoid fever. As before stated, tuberculosis of

*Read before the Minnesota Academy of Medicine, December 5, 1894.
†Gould's Dictionary.
joints may follow these diseases, yet how can they be distinguished?

Rhachitic joints, as a rule, are not hard to differentiate, as we usually have the general rhachitic condition to guide us. You may have the two associated or you may have, as I once saw, only one bone in the body showing rhachitic changes. Take, for instance, a rhachitic posterior curvature of the spine: you will observe quite an acute posterior angular curvature of the spine, irritability, and sleeplessness of the patient. If seen early, about the only distinguishing point in any way positive in the rhachitic spine is that, instead of being rigid as in curvies, it is very supple. I have pictures of a patient with a rhachitic posterior curvature of the spine which I was able to diagnose because of the general rhachitic condition and the case with which the spine could be flexed. To-day the kyphosis remains as you see it in Fig. 1, but the general rhachitic conditions have all disappeared. Had I seen the case for the first time in its present condition, I am sure I could not have distinguished it from curvies of the spine; in fact, it was lately so diagnosticated by a physician seeing it for the first time.

Effiphysisis, acute or supplicative, but not tuberculous, if seen before the joint becomes involved, is easily recognized; this, however, occurs within a few days, and occurring in childhood has often been taken for tuberculosis of the joints.

I never realized that neuromimetic or hysterical joints were so difficult to distinguish from really diseased joints, until I fell into this error in the case of a school teacher sent to me by a physician who diagnosticated knee-joint disease.

I found atrophy of the calf and thigh, slight enlargement of the knee joint, pain on motion, night pain, interference with the normal movement, and a tuberculous family history. The patient had just left a hospital in Philadelphia where she had been treated for the same disease. After receiving my opinion she left the office to make arrangements to enter one of the hospitals. On her way she met with a Christian Scientist, who proved to her that she had no disease of the knee joints, and I guess this was correct, for from her own account she has since been free from pain, etc.

For consolation in this I find in the Gazeta Lekarska No. 39, 1893, a case of hysteria reported by Gajkiewicz. Among other symptoms there was adenous swelling of the right arm and forearm; this swelling was hard, indolent, and persistent, but the skin over it was pale. This shows to what extent hysteria may carry one.

I now have under observation a young girl about fourteen years of age. She had undoubtedly a tuberculous knee, was extremely nervous, and, as poverty prevented proper nourishment, I insisted on her being sent to a hospital. Unfortunately, she was obliged to associate with three patients with hip-joint disease. The knee improved satisfactorily and in due time she was discharged from the hospital. While in the hospital she asked me one day to examine her hip, as she thought she too was getting hip-joint disease. I noticed that she held the hip quite rigid, but soon satisfied myself that she had no hip trouble, although I forgot, it seems, to inform her of this opinion. After she left the hospital I instructed the mother to have her walk about, watching the knee very closely, and if any unfavorable symptoms presented themselves to report at once. After a few weeks the mother returned and informed me with great concern that her daughter had now hip-joint disease and was a hopeless cripple. She had lost all control of her bladder. She cried.
continually, rolling and tossing on the bed, and exclaiming in a loud and excited manner that she wished she might die. I found the leg, thigh, and hip held in the characteristic position of hip-joint disease. Whenever I attempted to bring the popliteal space down upon the table there was the typical occurrence of lordosis of the spine; all the muscles of the hip were perfectly rigid, and I could get no movement of the hip joint; there was atrophy of the calf, thigh, and gluteal muscCles, and if it had not been that there was no shortening I might have been led to make a diagnosis of hip-joint disease. From her extreme nervous condition I suspected minicur, and after three or four examinations at intervals a week, I satisfied myself that my suspicions were well founded. Sending the mother from the room, and getting some one to distract the girl's attention, I straightened the limb and moved it freely in every direction. As soon as the sympathetic mother returned she immediately brought her limb into the position in which she had seen the other patients, and refused to walk. I have seen the patient a number of times since, and am sure she has nothing more or less than hysterical hip-joint disease.

Haemophilic joint disease is quite difficult to recognize, as the haemorrhage is from the synovial membrane. The symptoms given by Howard Marsh are as follows: "While bleeding is already taking place elsewhere, or as the first event is a haemorrhagic attack, one of the joints (the knee is a convenient example) is found to be the seat of a suddenly developed enlargement, sometimes only amounting to a slight, puffy swelling, but often distinctly fluctuating, and evidently caused by fluid in the synovial cavity. There is little increase of heat, but the joint is often painful on movement and tender, as if affected with subacute rheumatism. Subsequently the swelling gradually subsides, and the joint may entirely recover, but in many cases stiffness and pain, varying in amount in different cases, remain, and are accompanied by frequently relapsing attacks, which prevent the patient from walking. In some instances the joints become more and more impaired by repeated hemorrhages and the inflammatory attacks to which they give rise." I have seen but one case, and this, as regards the history about the knee, was much the same as to symptoms as is stated by Mr. Marsh; but the history of the haemorrhagic diathesis was not discovered until repeated hemorrhages followed the excision of the joint.

Loose bodies in joints may occur without any trauma, such as masses of condensed fibrin pressed into shape, or connective tissue and fat, or a sort of albuminous material which seems to be a conglutination of the synovial fluid. Of course, the acute attack will help in the diagnosis; but, after repeated attacks of pain and locking of the joint, the patient is quite likely to get a chronic inflammation.

Mrs. B., aged fifty-three years, was admitted to St. Luke's Hospital and assigned to me for treatment, giving the following history: Since ten years of age she had had more or less pain in the left knee, varying according to rest and use. She was very thin and small of stature.

There were extreme atrophy of the leg, enlarged knee, rounded and spindle-shaped, with marked thickening of the synovial membrane and some abnormal fluid in the knee; shortening of the leg, pain on motion, the knee flexed, and neuro-muscular spasms of all the muscles about the joint. I informed the patient that I feared she was suffering from tumor albus, or rather white swelling, and she remarked that she had often been told this by physicians. I applied a plaster of Paris cast, but was unable to straighten the leg. I then resorted to extension by weight and pulley, again meeting with failure so far as the straightening was concerned, but the synovitis was greatly improved, and the spasm of the muscles was also disappearing. I was able to flex and extend the joint up to a certain point, where I met with a sudden check. Realizing some mechanical obstruction and using my entire strength, I could feel a sudden slipping or giving within the joint, and with a quick snap the knee was completely straightened. As soon as my patient recovered from the shock caused by the pain, she exclaimed: "There, I have been dreading that, I have been dreading that ever since I came to the hospital, for I knew it would have to happen before you could get that old leg straight." Then, by considerable coaxing and suggesting, she was induced to give a typical history of a loose body within a joint.

Bursitis, while not a common disease, is met with, the hip and knee probably being the only positions where it might be confused with true hip-joint disease or white swelling. About the hip, when the obturator internus bursa is inflamed, the tumor of the bursa here must be distinguished from a beginning abscess. One can readily understand how the joint would be more or less fixed by the spasm of the muscles. In the knee a large bursa may develop in the quadriceps tendon (the subquadricipital); this often opens into the joint.

In traumatic joints, where it runs a chronic course, it is very difficult to differentiate from a true tuberulous disease of the joint, for we well know how often a tuberulous joint disease dates from an injury. We know, too, that in tuberulous diseases of the joints there are two great classes pathologically, one which begins in the soft parts and the other in the bone, resembling two forms of traumatic synovitis—synovitis with effusion and dry synovitis.

Dry synovitis is a disease which rarely attacks any joint but the knee, and often occurs in rheumatic patients. How difficult to distinguish from tuberulous joint beginning in the bone! It would hardly seem possible for incised wounds of joints to confuse us. Permit me to cite a case:

A young man in this State is under my care with a partially ankylosed knee, with a large eciatrix near the inner border of the patella, which, he informs me, followed an injury that occurred about a year and a half ago. He still has pain, flexion, and extreme atrophy of the calf and thigh. After considerable questioning he stated that at the time of the injury, which occurred nine months before I saw him, there was a slight abrasion of the skin at the site of the present scar. Has this young man a tuberulous knee or simply a traumatic joint with an incised wound followed by suppuration and destruction of the joint?

In gouty joints it would be only the chronic form which would puzzle us, or the so-called hereditary form, if such there be.

Tumors of joints are neoplasms originating, in or about the articular ends of the bones, and for our reputation's sake must be early distinguished from tuberculosis.

Syphilitic joints are, I am sure, very common and closely resemble, especially the hereditary form, tuberculosis of joints. My only means of distinguishing them is by close observation and by asking very embarrassing questions of the parents. If one is in some doubt, a persistent use of mercury will soon decide the question.

Seborrheic Joints.—So far as the records in the United States show, the first case of a child suffering from seborrhöa was seen at the Foundling Hospital in New York in 1889. No diagnosis was made in this case, however; the patient died, and the post-mortem first revealed the true nature of its disease.

During a recent discussion on infantile scrobutus at the New York Academy of Medicine several cases were cited where the swellings of the articualar ends of the bones of the lower extremity had led to error in diagnosis.

There was one case reported in which a swelling about the knee had been diagnosed as sarcoma; another, tuberculous osteitis of the knee; and a third, infantile paralysis, on account of the helpless condition of the legs.

Dr. H. L. Taylor had seen a case that had been taken for Pott’s disease and for hip joint disease. Of course, the spongy or bleeding condition of the gums and the history and general appearance of the patient would be all that would assist in distinguishing it from tuberculosis.

From the fact of so many prominent men having made errors in diagnosticating the cases just reported, and from the recent discovery of this disease affecting the joints of infants, I feel quite sure the statistics of tuberculosis have been increased.

Dr. Royal Whitman has read before the American Orthopedic Association an article entitled Bending of the Neck of the Femur in Adolescence. He called attention to a deformity of the hip joint which develops in adolescence, occurring at a period of rapid growth, during weakness and instability of the bones which are subject to overwork or strain by occupations necessitating long standing or the carrying of heavy burdens.

The symptoms which were presented were as follows: “Without apparent cause, or following a slight injury, the patient begins to limp and to complain of fatigue and pain about the affected joint on motion. Shortening of the limb is soon apparent; the limb is usually slightly rotated outward, extended or slightly flexed; the motion of the joint is somewhat limited, particularly in abduction; there is no local swelling or tenderness on pressure. Naturally the shortening is due to the elevation of the trochanter above Nélaton’s line.” How easily one might fall into the error of diagnosticating such a case as tuberculous disease of the hip! I recall only one such case in my own practice, and I assure you the parents grew quite anxious before I succeeded in finding the cause of the pain, shortening, and slight pain on abduction, of which she complained; in fact, I believe the only reason I did not make an immediate diagnosis of beginning tuberulous hip-joint disease was because there was no atrophy. I had the antecedent history in this case of tuberculosis, but, as the young woman was extremely fleshy, I suspected bending of the neck of the femur, and demonstrated to my own satisfaction that this was the trouble.

Lovett and Morse some time ago reported a number of cases which they designated transient or ephemeral hip-disease. It is a form of disease of the hip with the characteristic symptoms of the more chronic form, but of very short duration. I simply refer to it here, for, so far, the pathology is conjectural.

There is another form of joint trouble which I simply wish to mention—a trouble upon which the grandmothers lay so much stress and designate as “growing pains.” I am sure we all become acquainted with this term, because the liltty suggest it as the cause of every pain to which a growing child may fall heir. The pain is brought on by fatigue, strains, or exposure. I believe it is nothing more or less than a hyperemia or anemia of the epiphyses. It certainly seems far-fetched when we are mystified to such an extent that we confound osteo-sarcoma with tubercular hip-joint disease.

Three years ago I was asked to see a young woman who had come from the country to be relieved of extreme pain radiating about the hip and down the thigh to the knee.

I found night pain, some limp, extreme atrophy, and a slight sensation of roughening of the hip joint was conveyed to me while manipulating the hip. The family physician feared tuberculous hip-joint disease, but, as there was no spasm of the muscles or any shortening, and as he had treated her four years before for inflammatory rheumatism, I was confident that it was not tuberculous hip-joint disease, but must be rheumatic.

This was the last seen of the case until nine months later, when I was requested by a general surgeon to see a case of hip trouble with him. We discovered in this same case a tremendous osteo-sarcoma involving the entire shaft of the femur and the pelvis.

The following case I have reported before the North Dakota State Medical Society, but, as I have followed up the case and have a more complete history, I beg to be allowed to repeat it here:

A Case of Osteo-sarcoma simulating Hip-joint Disease.—On April 2d Mr. G., called at my house stating, that he had been directed by his family physician to consult me regarding his child.

He was anxious for me to go at once, as the little boy was suffering great pain, even more than he had during the preceding weeks, as the jolting in traveling from a neighboring city had greatly intensified his suffering.

Upon my arrival at the hotel I found the mother carrying in her arms a little boy two years of age, holding him in such a position as to keep the thighs flexed, which position she told me was the only one in which he seemed to be comfortable.

The parents noticed, about two months previous, that the child when playing had a slight limp; a little later it would scream out in the night as it frightened; still later it would have intervals of screaming and crying for some time during the night, the limp all the time becoming worse.

At last it refused to walk or move the left leg, or even allow it to be moved, and during an entire night would sleep but a few moments at a time. During the day, if the limb was not disturbed, it would seem quite comfortable.

The child had a pinched or weizened appearance, and certainly its face showed its suffering.

I noticed that it carried its left foot, the foot of the disease
limb, resting upon the right, which position, I was informed, it held night and day.

There was extreme abduction of the thigh, and I noted a slight fullness about the hip and enlargement of the inguinal glands.

When the child was laid on the bed the thigh was flexed to about a right angle. When I brought the popliteal space down upon the bed there was the characteristic lordosing of the spine. I could get little or no movement of the hip joint, due to the very great spasm of the muscles of the pelvis and thigh. Extension of the leg in the line of deformity seemed to give relief; at least, the child would cease crying.

I did not attempt the measurement of the limb as to length and circumference, as the examination I had made caused such excruciating pain. I will state, however, that I remarked at the time that the limb was not atrophied, as cases of tuberculous hip-joint disease are, and that it looked to me if anything a little larger than its fellow. As the child had phimosis and had some trouble in urinating, and as it would be necessary for me to chloroform the child for this, I informed the parents I would complete the examination for the hip at this time. However, I stated to them that from the history and present appearances their child was undoubtedly suffering from tuberculous hip-joint disease, and as the child had a temperature of 100° F., and from the enlarged hip and swollen glands, I diagnosed an abscess.

On the following morning I chloroformed the boy, and after relieving the phimosis I turned my attention to the hip, which, under the anaesthetic, was completely relieved of the neuro-muscular symptoms which were present before anaesthesia. The flexion was almost completely overcome; in fact, extension, flexion, rotation, and abduction were about normal. This made me more positive in my diagnosis of hip-joint disease, and just before applying the hip splint I determined to carefully examine the abscess, as I had not had an opportunity to do so before. Instead of finding fluctuation, to my surprise I found a marked induration, especially in the inguinal region, very little about the external aspect of the pelvis. When I made pressure in the pelvic region I was surprised to find that this induration would be felt by making considerable pressure, extending from the iliacus across to nearly the median line and within half an inch of the umbilicus. I then suspected for the first time that I had a case of osteo-sarcoma instead of tuberculous hip-joint disease. I informed the mother of my mistake in diagnosis and asked for counsel, and as she left the consulting of students to me, I assure you I called surgeons of no mean ability. We diagnosed an osteo-sarcoma. In examining by the rectum we found that the disease was very extensive; the sarcomatous tissue could be felt all about as far as the finger could reach.

It seemed surprising that the functions of the bowels had never been interfered with. The surgeons present agreed that there was nothing to be done for the child. This was about six weeks ago. I have since received a letter from the father stating that the tumor was increasing in size very fast.

I am aware that "osteosarcoma affects a neighboring joint comparatively seldom, even at times passing outside the articulation from one bone to another"; but I am quite sure that in this case, if not sarcomatous, there certainly must have been an inflammation of the joint to have produced the symptoms which were present, and that is my only excuse for having been so astray in my diagnosis.

This is the report verbatim as I gave it before the society referred to, but, as I was very anxious to follow up the case, I corresponded with the parents and family physician.

The following is my last letter to the doctor and his reply:

ST. PAUL, MINS., August 11, 1882.

MY DEAR DOCTOR: You will doubtless remember the case of Mr. G—'s little boy whom you sent me. I write you, as I am very anxious to know from a scientific standpoint what has become of the case, as it was a very unique one.

Fraternally yours,

ARTHUR J. GILLETTE.

To this his reply:

LONG PRAIRIE, August 12, 1883.

DEAR DOCTOR: Should have written as I intended to do about this case, but neglected it. The trouble was undoubtedly a deep-seated abscess within the pelvis, the contour as it arose in the pelvis leading one to think of osteo-sarcoma. My attention was called to the appearance of the parts by the parents, not long after returning, and I could easily see that it was a large pelvic abscess. I hanced it freely just external to the femoral vessels, and there was immediate relief. Whether it was connected with the hip joint or not I could not say, but the little fellow is all right to all appearances, walks well, sleeps well, and eats heartily. Excuse me for not writing before. Any further information I shall be glad to furnish. Yours truly,

THE ETIOLOGY OF STRicture of the Male Urethra, with Special Reference to Its Relations to Gleet.*

BY W. W. STEWART, M. D., M. R. C. S.,
SURGEON TO EMBRY HOSPITAL, PITTSBURGH, PA.

Few subjects in the literature of medicine have been more generously dealt with than the one which forms the title to this paper. This subject has been, and still is, prolific of discussions, most of which have, however, been fruitless, and have tended but little to the elucidation of the truths which underlie this vexed question.

It is but a comparatively recent period since the urethra was almost a terra incognita. The facilities for examining it during life were imperfect, and the opportunities for examining it after death were neglected. Its pathology was in a chaotic condition and its treatment was unsatisfactory. This was especially so in the diseases of the urethra which were accompanied by a chronic discharge called gleet.

Until about a quarter of a century ago gleet was simply recognized as the mucous-purulent discharge resulting from a chronic inflammation of the urethra; no well-defined ideas were entertained regarding its causation further than that it was usually an imperfectly cured gonorrhoea. The unsatisfactory status of its pathology, and the equally unsatisfactory results of its treatment, made the period ripe for the reception of views radically different from those that had been previously entertained and from the criterion of results found wanting.

At this period Professor F. N. Otis, of New York, came to the front as the promulgator of views on the etiology of gleet which reduced its pathology and treatment to a very

---

* Read before the Pittsburgh Academy of Medicine, October 22, 1894.
simple basis. The teaching of Professor Otis was not only widely disseminated, but received a general credence from the medical profession of this country, and soon established a new school of urethral surgeons. The followers of the new and the adherents of the old school of genito-urinary surgeons were soon engaged in a heated controversy which waxed for years around the battlefield of gleet, with varying degrees of success on either side.

The two schools still stand arrayed against each other, although the line of demarcation has become less distinct; many of the foremost adherents of the new school have recanted, at least in part, the doctrines they once enthusiastically upheld.

The theories promulgated by Otis concerning the caliber of the urethra, and more especially on the causation of gleet, were so antagonistic to those previously entertained, and have had such an important bearing on the treatment of both stricture and gleet, that they will be entered into somewhat in detail as a preliminary to their further consideration. Condensed into the smallest compass, Otis taught that the normal urethra was practically a tube of uniform caliber which bore a definite proportion in size to that of the penis, and that any deviation from the uniformity of its caliber whereby the dilated urethral canal was narrowed was not only pathological in itself but was also capable of producing or perpetuating a gleet.

To quote his own words, in his book on Stricture of the Male Urethra, page 20: "As the urine is propelled through the urethral canal it impinges with more or less force upon any contracted or salient point. The column of fluid is arrested, and in proportion to the degree of arrest is the force of the blow upon the mucous surface at this point. More or less hyperemia necessarily ensues, and a condition is soon established well adapted to prolong an existing gonorrhea, or which upon slight additional cause, such as venereal excitement, or even an unusually acid condition of the urine, may result in the origination of a muco-purulent or purulent secretion.

"We may hence affirm as a most important axiom that the slightest encroachment upon the caliber of the urethral canal is sufficient to perpetuate a urethral discharge, or even, under favoring conditions, establish it de novo without venereal contact."

On page 55 of the same work there appears the following: "Chronic urethral discharge, commonly called gleet, is the signal which Nature hangs out to notify the intelligent surgeon that an obstruction to the normal working of the muscular apparatus of the urethra has occurred, that plastic material laid down in the antecedent inflammatory condition has begun to contract the normal urethral caliber, whether it be twenty or forty millimetres in circumference, and that nothing short of a complete restoration of the normal caliber will afford a permanent cure. Sandal oil may stop it for a time, injections of innumerable variety may try one of them remove it, but a little vicious or venereal excess will reproduce it, and thus the case goes on getting, as many such cases will affirm, a new clap for every woman looked at, until finally an attack of retention of urine calls attention to the fact that the patient has a strictured urethra."

The teaching of Professor Otis that gleet owes its origin and existence to a stricture, however slight it may be, and the natural sequence that the cure of the gleet depended upon the removal of the obstruction to the passage of the urine, reduced the treatment of chronic urethral discharge to a very simple basis: first find the stricture and then remove it.

The simplicity of this rule, the dogmatic manner in which it was enthusiastically taught, the mathematical precision of it, as it were, by which the road to success in urethral surgery was easily trod, contrasted so strikingly with the devious and uncertain ways in which the older surgeons taught us to wander that it is not to be wondered at that an army of practitioners enthusiastically and blindly adopted this rule of treatment, with the result that in the treatment of gleet there has been more pernicious activity displayed, more unjustifiable operative interference than in any other department of surgery.

The American literature on this subject is still strongly tainted by the views of Otis, and his disciples have ample authority behind which to intrench themselves in the defense of their views, for it is only necessary to refer to the standard works on the subject to determine the point in their favor by the weight of authority.

To illustrate what I refer to, I have selected the following from the works most frequently used by the American practitioner:

The American Text-book of Surgery, page 861; also the International Encyclopaedia of Surgery (Am. ed., vol. ii), page 358, referring to the classes of urethral discharge, says: "And those commonly known as gleet, which in almost every instance will be found associated with urethral coagulations, often of the sort known as strictures of large caliber."

Holmes's System of Surgery (Am. ed., vol. ii), page 980: "The author does not give sufficient prominence to the fact that the vast majority of gleety discharges depend upon the presence of stricture."

Ashhurst's Text-book of Surgery, sixth edition, page 1050: "One of the earliest symptoms of stricture in many cases is the presence of a slight gleet discharge."

Diseases of the Urinary and Male Sexual Organs, by William T. Belfield, page 90: "That a gleet discharge which has made the usual rounds among physicians and has for years resisted medication by injections and the passage of large sounds (12 to 16 English) is often maintained by a slight constriction of the urethral caliber, and completely and immediately relieved by the division of such constriction, I have repeatedly demonstrated."

Genito-urinary Diseases with Syphilis, by E. L. Keyes, page 135: "This frequency of micturition is the symptom of stricture, next to gleet discharge, which is least often absent."

Perhaps the most ardent advocate of the dependence of gleet upon stricture that has appeared in recent years is G. Frank Lydston, whose work on stricture of the urethra, issued during the past year, would almost out-Otis Otis. The
following is extracted from page 142 of this work. Speaking of strictures of the pendulous urethra, he says: "They are a potent cause of chronic urethritis and gleet, and explain the obstinacy of very many apparently incurable cases of urethral discharge. Even when they are not, strictly speaking, the cause of chronic inflammation, they invariably tend to perpetuate it.

"If the profession had nothing else for which to thank Dr. Otis, it would still be under lasting obligations to him for his demonstration of the true pathological condition in the majority of these obstinate cases of gleet which have so long been the *bête noire* of the surgeon."

We are not bound to accept mere statements as proofs, no matter how positively they are made, nor whose author is. At the same time it would be obviously absurd to condemn a theory so well supported and so generally fol-

lowed, as is the theory that gleet is dependent upon stricture, without good and sufficient reasons for so doing.

Before venturing to cite the writer's views on this subject it will be advantageous to first take up the consideration of the normal urethra as a preliminary to the further discussion of stricture and its relations to gleet.

The urethra in a state of quiescence is a closed canal, its mucous surfaces being retained in apposition by the elasticity and contractility of the connective and muscular tissues which invest it throughout its whole extent. It is only, therefore,

when the urethra is dilated, as during urination or instrumental interference, that a stricture is capable of demonstration.

When the urethral canal is closed or at rest its lumen may be represented by a capillary tube which conforms to the curves of the urethra, as in Fig. 1.

It is self-evident that the lumen of the urethra, if a lumen may be said to exist under such circumstances, is uniform throughout, with the possible exception of the portion comprising the fossa navicularis, where the urethral walls are seldom accurately coaptated.

When the urethral walls are separated by intra-urethral distention, the urethra as it unfolds itself and exerts a distending force on the peri-urethral tissues. Up to a limited degree of dilatation the urethra maintains a uniformity in its caliber; but as the dilatation increases the variability in certain portions of the urethra, not only of its own elasticity, but also of the resistance to displacement of the peri-urethral tissues, produces a variation in the caliber of the urethra which, at first sight scarcely recognizable, becomes on further distention very marked, as is shown in Fig. 2, and to a still greater extent in Fig. 3, where the distention is very great.

A few years ago the writer devised an instrument for taking a diagram of the dimensions of the urethra which is called a urethrogram (Fig. 1). This instrument is so constructed that it will take a diagram of the dimensions of the whole urethra under a uniform but adjustable degree of distention. The observations which I have made with the urethrogram have not shed a new light on the topography of the urethra, but have simply served to confirm the observations that anatomists have long since made—namely, that the distended urethra is a canal of variable diameter, no one part of which can be taken as a criterion of the dimensions of the other. Nor can one urethra be taken as the standard from which to judge others, so much do they differ from each other in their relative dimensions.

Not only does the lumen of one urethra differ from that of another, but each urethra differs from itself according to the degree of distention it undergoes. This is well illustrated in the following series of diagrams (Fig. 5) taken with the urethrogram from the same urethra under varying degrees of distention:

In studying these diagrams a word of caution is neces-
sary in order not to misapprehend the contour of the urethra. The line traced by the urethrograph does not represent the contour of the urethra, it only shows the diameter of the urethra in millimetres at all points measured from a straight base line.

The first diagram, or the one nearest the base line, shows the urethra under a moderate degree of distention. The second, third, and fourth diagrams show the urethra under a progressively increased degree of distention.

It will be noticed that the greater the degree of distention the greater the deviation from uniformity of caliber; and conversely, the less the degree of distention the more nearly uniform becomes the caliber of the urethra. As the distending force exerted against the urethral walls by the urethrograph was certainly greater in the diagram nearest the base line than would be exerted by the passage of a stream of urine, the inference is fair that the urethra under a degree of pressure equivalent to that exerted by the passage of a stream of urine is a tube of almost uniform caliber, and under these circumstances conforms to the views of Otis concerning the caliber of the urethra. The chief point of interest which these diagrams bear to the subject of stricture is that the healthy urethra as distended by the passage of a stream of urine is a canal of almost uniform dimensions, and the same urethra under a degree of distention no greater than is habitually exerted by the passage of urethral instruments shows marked irregularities in its caliber.

The caliber of the urethra is thus a fluctuating quantity, its variations depending on its degree of dilatation; no standard can be given as accurately representative of the normal urethra. Sir E. Home has given a cast of the normal urethra under forced dilatation (Fig. 6) which may be considered a fair representative of the overdilated urethra.

In a memorable controversy between Dr. Sands and Dr. Otis on this subject the former exhibited a series of casts of the urethra (Fig. 7) which illustrates the natural irregularities of the dilated urethra. Dr. Sands contended that these irregularities were present in the healthy urethra and were in no wise pathological. To this Dr. Otis replied that these irregularities were either pathological in their formation or, if not, would, by retarding the stream of urine and thus creating a point of increased friction, be capable of perpetuating a urethral discharge.

Since no evidence could be brought forward to prove the absence of a pre-existing urethritis in the cases from which these casts were taken, the arguments put forward that the irregularities shown were pathological in formation could not be refuted, although the weight of evidence was against such being the case. In considering this subject, it occurred to the writer that a series of casts of the infantile urethra would be representative of the urethra under conditions which preclude the possibility of pathological irregularities in its formation. The opportunity was therefore availed of to make a series of wax casts of the infantile urethra, casts of which are given in Figs. 8, 9, 10, and 11.

Fig. 8 was taken from the urethra of an infant two weeks old; the injection was made under water; the wax was forced into the bladder until a stream issued from the meatus which was estimated to be equivalent in force to that of a stream of urine. In a few moments the stream of wax solidified, the bladder and urethra were lid open, and the cast was extracted.

Fig. 9 was taken in the same manner from an infant two months old.

Figs. 10 and 11 were taken from infants aged six and nine months respectively.

In these cases the prepuce was surrounded by a ligature to prevent the escape of the injection, which was
forced into the bladder under a pressure almost sufficient to rupture that organ.

In comparing these cases the fact already pointed out is apparent—namely, that the urethra under a normal degree of distention has an almost uniform caliber, but under forced dilatation its caliber varies according to the degree of distention, so that no one part can be taken as the criterion of the dimensions of the other.

These facts are of the greatest importance in the consideration of the subject of stricture, and are in direct variance with the theories entertained by the followers of Otis, who maintain that the dilated urethra has an almost uniform caliber, and that a stricture may be of any grade of severity, from one which completely occludes the urethra to one which is only perceptible on forced dilatation of the urethra, the latter being as true a stricture as the former, each having the vicious properties in greater or less degree of capability of retarding the stream of urine, and of perpetuating a urethral discharge.

It is an incontrovertible fact that a stricture may narrow the stream of urine or occlude it entirely, but in order to do this it is evident that it must, in the light of what has been said on the subject, be a well-defined stricture, and be capable of demonstration by instruments which do not dilate the urethra to a greater degree than is exerted by the passage of the stream of urine. We have seen that the overdilated urethra exhibits well-marked points of contraction which are not perceptible under a degree of pressure equivalent to that exerted by the passage of a stream of urine. Therefore these points that are only elicited by over dilatation of the urethra can in no wise be considered as acting as points of increased friction or of retarding the stream of urine, and are as innocuous from this point of view as if they never had existed.

Abnormal coarctations of the urethra which are insufficient to narrow the stream of urine are not strictures in the true sense of the word and by some writers do not receive recognition. Sir Henry Thompson defines stricture as "a deposit of lymph around the canal of the urethra at some point which, not permitting it to open to the pressure of the stream of urine, narrows the current to a greater or less extent."

The lumen of the male urethra is such a variable quantity that no definite size can be fixed as the one which would constitute the limit between a strictured and a non-strictured urethra. Since pathogenic properties have been attributed to even the slightest coarctations in the dilated urethra, their recognition is necessary. We may therefore divide strictures into two classes, the true and the false, or in the generally accepted classification of strictures of large and small caliber.

Strictures of large caliber may be defined as those points of narrowing in the urethra which are not of sufficient extent to retard the flow or narrow the stream of urine.

Strictures of small caliber are those points of narrowing in the urethra which are of sufficient extent to retard the flow or narrow the stream of urine.

In referring to stricture of large or small caliber in the remainder of this article this definition will be strictly adhered to. A stricture of large caliber may be and often is perfectly innocuous, but the baleful effects of a stricture of small caliber are too often made manifest. By obstructing the flow of urine it may be the starting point in a series of calamities which not infrequently terminate the existence of the patient, as many a surgical kidney can attest.

Stricture of the urethra may be due to a variety of causes, chief among which are the following:

1. Tonic contraction of the circular muscular fibers of the urethra, producing spasmodic stricture.

2. New growths which encroach upon the lumen of the urethra.

3. Urethral and peri-urethral exudates of an inflammatory origin which have not undergone organization.

4. Cicatricial contractions following injuries, false passages, and caustic applications or injections.

5. Gonorrhoeal infection of the urethra, which produces in its chronic form a specific type of urethritis which goes on to the formation of stricture tissue.

The first three varieties are not, in the strict sense of the word, strictures, and as they have but little bearing on the subject under discussion they will be considered but briefly.

Spasmodic stricture is produced by a tonic contraction of the circular muscular fibers of the urethra. These fibers are present to a marked extent at the apex of the prostate gland, where they form the external sphincter of the bladder.

Fig. 12 shows the situation of these circular muscular fibers of the urethra and the effect on the posterior urethra of a distended bladder.

It is the inability to relax at will the sphincteric action of these muscular fibers that produces the retention of urine that is so frequent a concomitant of operations on the rectum or perineum. This variety of spasmodic stricture
is but transitory in its nature and is entirely foreign to the subject on which this article is written.

True spasmotic stricture not due to such causes as the above is very rarely met with, and where present it will usually be found associated with some pathological condition of the urethra, most frequently a granular urethritis with the formation of stricture tissue at the site of the spasmotic stricture, or in rare cases at a distant point. So rare is this form of stricture that its very existence has been doubted. A case recently under the writer's observation is so typical of this class of stricture that it is here briefly reported.

A gentleman while still a youth contracted a gonorrhoea which invaded the posterior urethra and set up a cystitis. After a few months this was followed by retention of urine requiring the use of a catheter. Since that date retention has been constant for a period of twenty years.

On examination, a No. 27 F. steel sound could be readily passed into the bladder, although it was firmly grasped at the membranous urethra. A No. 8 F. soft bougie was grasped with equal firmness at the same place. To test this point an endoscopic tube was passed through the stricture and withdrawn until its extremity rested against the anterior surface of the stricture. A filiform bougie was then passed along the tube and through the stricture, by which it was tightly grasped, demonstrating the muscular element in the stricture. The endoscopic examination showed that at this situation patches of the urethra had undergone cicatrization, and it is probable that it was the irritation due to the contraction of the cicatrical tissue on the terminal filaments of the nerves that caused the spasm of the muscular element of the stricture.

External urethrotomy was performed. The division of the stricture restored at once and permanently the patient's ability to urinate at will without the use of a catheter.

Strictures resulting from the encroachment of new growths or the formation of retention cysts are not in the strict sense of the word strictures, and their consideration further than the mere mention of their existence would be to encroach upon the space intended for the consideration of subjects more relevant to that under discussion.

It should not be forgotten, however, that all the obstructive symptoms of a true stricture may be present, and in the papillomatous form of tumor there may also be present an obstruse urethral discharge.

Strictures produced by urethral and peri-urethral exudates of an inflammatory nature which have not under-gone organization are sometimes called soft strictures and sometimes inflammatory or irritable strictures. They owe their existence to a recent and perhaps still active inflammation of the urethra, usually acute gonorrhoea.

In acute urethritis the mucous, submucous, and occasionally the cavernous tissue is infiltrated by serum and leucocytes. In addition the epithelium of the urethra is stimulated to increased cell proliferation, the resultant being a urethra with thickened walls and diminished resiliency, which may be of such a degree as to narrow the stream of urine, and for the time being be classed among the strictures of small caliber.

On the subsidence of the inflammation the urethra gradually returns in the majority of cases to its pristine condition, but in a respectable minority resolution may not be complete. A condition of chronic infiltration may persist for a time, to either ultimately undergo absorption or in rare cases organization with the production of true stricture tissue.

There are too many observations confirmatory of the latter change to permit of its being controverted, but I venture to predict that the pathological investigations of the future will show, if it has not already been demonstrated, that this process in the formation of true stricture is far from as common as is generally supposed.

Under the head of traumatic stricture are classed all strictures resulting from traumatism, such as direct injuries from without or from within, as by unskilful use of instruments or the application of caustics or corrosive injections.

When the urethra has been subjected to traumatism of such a degree of severity as to lacerate it, a splice of new tissue fills the rent and the foundation of a stricture is laid. If the rent be small, the plastic material laid down to repair the injury may not be sufficient to produce by its subsequent cicatization and contraction a perceptible diminution in the expansibility of that portion of the urethra and no stricture results; if, however, the laceration is severe, as occurs in complete rupture of the urethra with separation of the torn ends, the resulting cicatization of the new material produces a most intractable stricture which requires the utmost watchfulness and patience in order to maintain a sufficient patency of that portion of the urethral canal.

The rapidity with which this variety of stricture forms is astonishing; and is in marked contrast to the formation of the next variety of stricture. The following case illustrates this rapidity of stricture formation. It was a complete rupture of the membranous urethra, with extravasation of urine, and was treated by retrograde catheterism. A soft catheter was retained in the urethra for three days, after which a No. 28 F. steel sound was passed with ease on every alternate day for a period of three weeks, when the treatment was abruptly terminated by the elopement of the patient from the hospital.

Five weeks later the patient reapplied for treatment. An examination of his urethra showed that there were good reasons for the sincerity of the penitence he manifested at his self-imposed curtailment of his treatment. The cicatization of the new material that sealed the torn

ALLEN: EFFECTS OF CRETINISM ON THE NASAL CHAMBERS.

BY HARRISON ALLEN, M. D., PHILADELPHIA.

Medical observers in America have had little opportunity of studying cretinism. But I believe that we are apt to make a mistake in not bearing in mind the possibility of this morbid condition being met with in our clinical services. In metropolitan hospitals examples of cretinous dwarfs are not rarities. As for the conditions described by European writers as those of semi cretins and cretinoids, I believe that they are numerous, but are not so often sought for as they should be.

According to F. R. Sensberg (Der Cretismus mit besonderer Rücksicht auf dessen Erscheinung im Unter-Main- und Rezat-Kreise des Königreiche Bayern, Würzburg, 1825), the skull in cretinism is not of a single type. In the true cretin, that is to say, one associated with goitre, with deep nose root and a bulldog-like head, the skull is thick, the occiput is flat, the sides of the head are broad and usually asymmetrical. The sutures are disposed to disappear early or at least irregularly. Virechow (Untersuchungen über die Entwicklung des Schädelgrunds in gesunden und krankhaften Zustande und über den Einfluss derselben auf Schädelform, Gesichtsbildung und Gehirnbau, Berlin, 1857) describes an entirely different type of cretin skull from the foregoing. It exhibits a tendency to synostosis, while a disposition exists to excess as well as in unusual positions of the Wornian bones.

Another cretinoid skull is known in which the bones are thin and in various places are without diploic structure. The mastoid processes are weak. The Valsalvian foramen at the angle of the occiput is large, and the opening between the basilar process and the petrous portion of the temporal bone nearly obliterated, affording but a small space for the passage of the nerves. The basilar process itself is nearly horizontal, thus resembling the condition known as the soft occiput of Elsasser.

Roesch (Aun, Bericht über die Versamml. deutsch. Natur. u. Aerzte, 1842, 22, 238-245) describes a cretin's skull in which the occiput, instead of being flat, exhibits a capsule-like projection of the under part; the forehead is low and slightly rounded; the two halves of the head are apparently shoved one on the other ("die beiden Hälfte des Kopfs verseloben und die eine steht hinter der andern zurück"). This language of Roesch is somewhat figurative, but doubtless refers to the fact that the two frontal eminences are asymmetrical, as also are the two sides of the occiput, that side of the occiput which projects farthest corresponding to the side of the skull at which the frontal eminence recedes. This peculiarity of the cranium is by no means confined to the cretin, but is mentioned by other writers, and is ordinarily attributed to Broca; the observation is thus found to be anticipated by Roesch by many years. Roesch describes another form of the skull—namely, the one in which the bones are thin. The dimensions are too small. The form of the skull is rotund; it may be so high on the sides as to constitute the sugar-loaf head (in some cases the occiput markedly projects, constituting what is called "cat head"), while all prominences and muscular impressions are inconspicuous.

I herewith exhibit two specimens of skulls belonging to the Wistar and Horner Museum of the University of Pennsylvania, showing what I venture to call cretinoid deformations; they are without history, but they conform in a manner sufficiently exact to the descriptions of foreign writers to permit me to so identify them.

In one of these specimens the bones are thick and appear to be imperfectly calcified, while the nose is prominent, the facial portions are stunted, the hard palate being small. I call attention particularly to the projection of the occiput; the occipital bone appears to have effect ed union with the parietals in such wise as to present a conspicuous depression between them. This appearance is called by some of the older writers "cat head" (Roesch, supra); it is by no means an uncommon contour, and can readily be detected in living subjects.

In the second example I show you of cretinoid deformations the nasal bones, instead of being prominent, are inconspicuous; indeed, one may say that there is no bridge to the nose, for the nasal bones, instead of being inclined forward and downward, are vertically disposed, and do not project in the least beyond the plane of the ascending processes of the maxilla. It might at first sight be inferred that this was nothing more than the "falling in of the nose" as a result of loss of the normal structures by the ravages of syphilis; but the most casual observer will be convinced that this skull was not taken from a syphilitic subject. As in the first specimen, all the facial portions are dwarved, the bones are thickened, and the hard palate is small.

In both specimens the inferior turbinated bones are
lodged high up in the nasal chambers and give the impression of being of great size. It is probably owing to the extreme shortening of the face that a compensatory growth occurs in these bones in the vertical direction, the posterior nares in both specimens being disproportionately large. The floor of the nose is greatly depressed below the level of the anterior aperture. The frontal regions in both specimens are broad and thick, giving the appearance of the so-called "apple head" in dwarfs. The suture between the halves of the frontal bones is apparent.

Bearing in mind the immense variety of appearances that one can secure in phases of malnutrition as affecting the head, and remembering that one must not expect to institute exact standards of comparison in studies of this kind, enough remains for me to be willing to state that the nutritive and developmental processes are evidently at fault in the cretinoid skull. In patients in whom I detect a bulb-like forehead with unnaturally projecting occiput, with depression between it and the parietal bone, where the external nose is dwarfed (or even, as opposed to this, the nasal bones are preternaturally high), the hard palate is small, and the posterior nares are of inordinate size, I should not hesitate to characterize such individuals as being cretinoid. If these conditions exist in persons of small stature (here not speaking of typical dwarfs) I should feel more than ever satisfied in using such a term in describing them.

These remarks are made with the hope that further observations may be elicited on the subject at the hands of those having large opportunities in public services. In these days of extensive immigration which brings large numbers of the impoverished class of Europe to our shores, it is not irrational to assume that many examples of "semi-cretins" or "cretinoid" individuals may be recorded. It is evident that important phases of prognosis and treatment of diseases of the nose and throat enter into conditions of this kind, and that all states of the development of the head should be known in studying the diseases of the nasal chambers.

**THE GOLD PREPARATIONS IN SOME SKIN DISEASES AND SYPHILIS.**

By A. H. OHMANN-DUMESNIL, A. M., M. D.,
Professor of Dermatology and Syphilology in the Marion Sims College of Medicine, St. Louis; Consulting Dermatologist to the St. Louis City and Female Hospitals; Dermatologist to the Alexian Brothers Hospital, Tus Hospital, Rebekeah Hospital, etc.

There are so many preparations of a novel nature, or which are merely revivals of old ones in a new form, being daily offered to the medical practitioner that he is often at a loss whether to use any of them. Not content with the inherent qualities of these preparations, their promoters either vaunt them as universal panaceas or construct the reading matter so clumsily that one naturally inclined to test the efficacy of the drugs calmly puts them aside until such evidence is forthcoming as will prove convincing and be clearly set forth. It is for this reason that clinical experience is so valuable when based upon careful observation and a knowledge of the conditions present.

Our knowledge of the therapeutical action of gold has, up to within a few years, been based upon the hypothetical dicta of the alchemists. Gradually the matter was taken up again, at first by the Arabian physicians and afterward in Europe. Once more it fell into disuse, and was rescued from oblivion by Hahnemann, who introduced it in his pharmacopoeia. However, this did not give it much of an impulse, and it is only of late years that this metal has undergone any serious investigation concerning its therapeutical properties. Among American investigators Bartholow, Heneage Gibbs, and Shufle are the most prominent. Dr. Shtcherbok has made thorough investigations also.

The most active salt of gold is the bromide, and it is particularly so upon the nervous structures, but small doses being necessary to produce effects. The action of gold is essentially that of an alterative. It has no cumulative effect; but, when toxic doses are administered, mental excitement, amounting to delirium at times, manifests itself. A prominent symptom of its excessive action is an extensive flow of saliva, the so-called aurism. Remembering this in connection with the fact that very small doses produce the effects of the remedy, more especially in the form of the bromide, some care should be exercised in its administration. Among the therapeutic effects of gold may be noted the fact that it is tonic, more especially to the nervous system, and this accounts for the fact that it is an aphrodisiac of no mean power. It was highly esteemed many years ago as an antisyphilitic, and recent experience confirms this view, more especially in the later forms of the disease.

The cutaneous troubles in which I have had occasion to employ the gold preparations to any extent are limited. In acne and eczema of a subacute or chronic character I have found arsenauro an invaluable adjuvant. On the other hand, in chronic eczema and in the later manifestations of syphilis mercurauro has proved itself almost a specific, so much so that its administration was always attended by marked improvement, which ceased so soon as it was discontinued. This it was which attracted my attention to the gold preparations, and in investigating their therapeutical properties I have been impressed by the fact that the most active as well as most efficient salt of gold is the bromide. It not only acts powerfully when administered alone, but seems to increase the therapeutic effects of arsenic and of mercury, and for that reason much smaller doses of these agents may be given, better results obtained, and, at the same time, security from toxic effects will be secured. These are the qualities which recommend the preparations mentioned above, which are true chemical combinations and not empirical mixtures.

It may not be inappropriate to mention a few cases from practice illustrative of the good effects of gold preparations in diseases of the skin and in syphilis:

**Case I.**—Miss F. B., a dark blonde of seventeen years, has been suffering from a marked pastular aene for two years. She is very nervous in disposition. Vlemingk's lotion ordered applied at night, and resorcin ointment every morning. In addition, the pustules were emptied thoroughly every day. Some little improvement showed itself, but it was not stable. A "nervous" attack would cause the eruption to manifest itself in a marked relapse. After two months of this treatment, with
OHMANN-DUMESNIL: GOLD PREPARATIONS IN SOME SKIN DISEASES.

variations of the external measures, she was placed on ten drops of arsenauro three times a day. In one week the eruption had disappeared, and now, after a lapse of two months, no lesions have appeared.

Case II.—Miss R. R., a blonde of eighteen years, states that she has been suffering from a papular acne, with comedones, since she was thirteen years of age. Free incisions of the papules, together with a sulphur ointment locally, failed to procure any decided effects until arsenauro was used. Her face is now perfectly smooth and clear and downy.

Case III.—Miss M. P. was suddenly attacked by an intense pruritus, accompanied by a mild form of ichthyosis. The ordinary antipruritic solutions did not allay the itching. The peculiar form of pruritus, together with the ichthyotic condition (not congenital), pointed to a central origin of nervous nature. Added to the antipruritic solution was arsenauro, administered in ten-drop doses before each meal. Improvement set in almost immediately, and at the end of three weeks the patient was cured. This occurred despite the fact that the trouble had lasted about a month before I treated her, and despite all the local treatment which she had been given.

Case IV.—G. R., a man of about sixty years, has suffered from general pruritus for several years. At the time he applied for treatment he was emaciated and haggard from loss of sleep due to the obstinate itching from which he suffered. He could only rest after complete exhaustion, and even then sleep was not only not enjoyed, but lasted for the briefest periods only. He presented many of the symptoms of neurotism. An antipruritic lotion, to be applied three times daily, and arsenauro, in fifteen-drop doses before meals, have markedly ameliorated his condition. He bids fair to make a complete recovery in a short time.

Case V.—Miss M. Z., a girl of twenty-four years, has been troubled with a rosacea involving almost the entire face for a period of four years. She is of a markedly nervous temperament, and her skin will become congested visibly if she gets excited in her conversation. The best reducing agents used externally have had but little influence upon the cutaneous affection. Her stomach was not in order, the trouble being, apparently, so-called nervous dyspepsia. Bearing in mind the close relationships between rosacea and gastric disorders, she was ordered five-drop doses of arsenauro before meals in addition to local applications. Marked amelioration of the gastric and dermal symptoms appeared, and now she is practically cured.

Case VI.—Miss H. L., a strong, stout girl of seventeen years, has suffered for a long time from turticaria. A close examination of her case shows that she is intensely susceptible to nervous perturbations. She complained of slight gastric crises at times, which disappeared spontaneously, but were always accompanied by a marked urticarial eruption involving the entire integument, including the scalp. While an antipruritic relieved the condition temporarily, internal measures failed to procure relief until fifteen-drop doses of arsenauro were given and diminished gradually to ten drops three times a day, until the condition was relieved. This relief has now lasted for four months with no indications that the disease will recur.

Case VII.—Mrs. R. B., an old lady of fifty-seven years, had been troubled with a marked case of eczema for a number of years. Her chest, back, arms, and thighs, as well as abdomen and breasts, had been the seat of a most intensely itching papular eczema for years. Her forearms and legs were affected with the squamous form of the same disease, the folds of the elbows and the popliteal spaces presenting marked fissures. Constipation which existed was relieved by the acid aperient mixture, and an antipruritic lotion followed by a menthol ointment partially relieved the patient. After a time the condition remained in statu quo. As no improvement would appear, she was placed on ten-drop doses of mercuro three times a day, and the dose increased until she took twenty drops at a dose. Improvement was noticeable to such a degree that in one month no traces of the eczema appeared. She was continued on the remedy for two weeks longer, and has continued well ever since, a period of about four months.

Case VIII.—Mr. C. H., an old gentleman of eighty-two years, was troubled with marked eczema of a squamous nature localized upon the backs of his hands. Being placed upon the same treatment as Case VII, much more rapid results were observed. He had had numerous relapses, however, due to the fact that he will handle mortar and similar irritating substances, including frequent washing of the hands. A strict adherence to injunctions, however, is always followed by a rapid return to the normal. Of course, water externally is always prohibited in these cases of eczema.

Case IX.—Mr. A. F., a young man of thirty-two years, applied for treatment for undefined pains in the head and swellings of the forefinger and thumb of the right hand, on the left ramus of the jaw, and over the right clavicle. He had contracted syphilis some five years before. He was given mercuro in fifteen-drop doses, to be increased five drops every week until thirty drops were taken thrice daily, or until vertigo declared itself, when the remedy was to be discontinued for a time. Marked effects for the better declared themselves long before the thirty-drop doses were taken. These latter had to be discontinued after a week on account of the vertigo which declared itself. The swellings, however, had gone down, the backache and headache had disappeared, and the patient slept quietly and was refreshed, something he had not known for a year previously. He resumed the treatment after a rest of two weeks and feels strong and buoyant instead of weak and melancholic.

Case X.—Mr. O. W., a married man of forty-three years, contracted syphilis about two years and a half ago. The condition remained unrecognized for about six months. He then applied to me for treatment. His symptoms disappeared rapidly under active mercurial treatment, followed by the mixed. I lost sight of him for about a year, when he applied for the relief of a bursa of the left knee which had been cut open by a surgeon. It returned, and he was advised an elastic knee cap and placed upon mercuro in twenty-drop doses three times a day. The bursa gradually reduced, and the patient, deeming the elastic bandage sufficient, discarded the medicine. The effusion began increasing and he quickly resumed the mercuro, and I had the satisfaction of observing the effusion entirely disappear. This patient indulged in increased doses which brought on vertigo. This symptom disappeared, however, upon resuming the original quantity. So far as any other syphilitic symptoms are concerned, they are not evident, and the patient feels both cheerful and contented.

These cases have been roughly outlined so as not to weary the reader. They are what might be called sample cases from a large number of similar ones which have terminated favorably under the influence of the gold preparations mentioned. One feature which has been particularly noticed in connection with mercuro is its marked aphrodisiac properties. While only male patients have mentioned this, no doubt the female ones experienced similar sensations or exhilaration. This latter has been alluded to by a number of patients of both sexes. There is no doubt in my mind that the bromide of gold is the most efficient salt of the metal, and it appears to exercise a two-
fold effect therapeutically—viz., it increases the action of the arsenic and mercury with which it is combined, and at the same time it seems to prevent the manifestation of toxic symptoms. It is itself very efficient, if we are to believe competent authority, which states positively that from the gold is thirty times as efficient as the other bromides.

So far as the preparations mentioned are concerned, they are efficient and rapid in action and the manifest effects of the gold are evident. An exact dosage by means of measuring the drops is attained and ease of administration is secured, no disturbance of the stomach resulting from their ingestion. The vertigo which is experienced disappears as soon as the dose is diminished. I have had no occasion to observe aurism up to the present. In fact, I have seen none but the good effects of these gold preparations. One point, however, must always be borne in mind. The indications presented must be such as demand gold. Some of the older writers maintained that gold was the remedy for syphilis, whereas it is only in the later and deeper manifestations that its good effects are shown. Furthermore, gold and its preparations will not have good effects in all skin diseases, but will prove a most valuable adjuvant in such as have a distinct neurotic base as an aetiological or complicating factor.

It is the hope of the writer that the few clinical notes jotted down above may serve as a stimulus to further inquiry into the therapeutical worth and more extended application of gold and its salts, as it is a matter of interest and possibly of the greatest importance, more especially in the treatment of many chronic affections of viscera and organs.

WHAT IS TUBERCULIN?

By KARL VON RUCK, B. S., M. D.,
ASHVILLE, N. C.,
DIRECTOR OF THE WINTAH SANITARIUM FOR DISEASES OF THE LUNGS AND THROAT.

This is the title of an open letter by Professor Charles Denison, of Denver, Col., published in the Colorado Climatologist, November 15, 1894.

In a personal letter received from Dr. Denison, on the 13th inst., he requests me to reply to the letter, and I am the more glad to comply with this request, inasmuch as I am able to join with my own the views of Professor Edwin Klebs, who is at present my guest.

In his open letter Dr. Denison objects to the statement from another source, that tuberculin is identical with poisonous products resulting from tubercular processes within the living organism, and also to the consideration of tuberculin as a toxine or a toxalbumin, and he bases his objections upon the favorable clinical results which he and others have obtained from its therapeutic application. These results, he maintains, justify the belief that the remedy is an antitoxine, and capable of producing a certain degree of immunity when properly applied in suitably selected cases.

Dr. Denison wants answers to two questions; first, Is tuberculin a toxine or antitoxine? Second, How is it made? And he wants answers either from Professor Koch himself or from some one who is thoroughly acquainted with this subject.

Before considering these questions, I desire to refer to the subject of bacterio-therapeutics in general.

The foundation principle of bacterio-therapeutics is the self limitation of the diseases produced by pathogenic germs, and the shorter or longer immunity to reinfection after recovery.

This principle finds partial elucidation in the fact that in artificial cultures of such bacteria a similar limitation is observed, and that the cultures after a time cease to grow and finally die out, long before the nutrient substances contained therein are exhausted.

The additional observation that such culture fluids, when the germs are filtered off, act germicidal to the particular species, whereas other specific forms grow and multiply freely upon the exhausted culture fluids, justifies the belief that this germicidal property belongs to the vegetation or rather secretion products of the particular kind, and that, the same as in man, these excrementitious substances are poisonous to their producers.

The immunity from recurrence of the same disease is more difficult to explain; but it is assumed that either through the products formed by the bacteria, or from their disintegration within the organism, the tissues of the previously infected organism become so modified that for a time their growth and multiplication are not longer possible, or that the organism tolerates the poisons which the bacteria produce, and thus the germs, although present, do not occasion the symptoms of the specific disease. Much may be urged for and against either of these theories; the fact remains that a greater or less degree of immunity as a rule results, and may be artificially produced.

There can be no doubt that the substances which destroy the disease germs, or which confer immunity directly or indirectly, are contained either in the bacteria or in their secretion products, and, so far as we approach a perfect condition of viruclency and favorable growth of the germs outside of the living organism, we may hope to obtain these substances from their artificial cultures.

It is well known that guinea-pigs are highly susceptible to tuberculosi; when they are inoculated with virulent cultures and with sufficient numbers of the germs the disease follows a rapid, definite, and fatal course. In Koch's experiments, made upon animals inoculated from the same culture, and with like quantities, the disease was allowed to develop to its unmistakable recognition; then certain of the animals were treated with tuberculin, while others for control were kept under the same conditions without treatment. In these control animals the disease pursued its usual fatal course, whereas the treated animals again improved, and outlived the control animals by considerable periods; some finally succumbed to the disease in the end, others were killed for examination, after various periods of treatment, and in the latter the evidences of previously present but healed tubercular lesions were unmistakably demonstrated, although more recent processes pointed also to the fact that the old lesions were not all entirely recovered from.
Professor Klebs took up this experimental work in guinea-pigs immediately after the announcement of tuberculin and carried it much further, and he has also shown that in guinea-pigs treated with tuberculin previous to tubercular infection the disease followed a much slower course, and that the tubercular lesions produced by inoculation had undergone retrogressive changes and in some cases entire cure.

So far as guinea-pigs are concerned, Professor Koch, and more particularly Professor Klebs, have proved beyond controversy that tuberculin has a curative influence, and the latter has also proved that it confers a certain degree of immunity, varying according to the time for which the treatment was carried out and the amount of tuberculin used.

The unexpected toxic effect of large doses of tuberculin in the human subject at once limited its use for the treatment of human tuberculosis, and, while guinea-pigs bore doses of several hundred milligrammes and improved under them, disaster followed from much smaller doses in man; and persistence in the use of large and evidently poisonous doses for therapeutical purposes brought the remedy into discredit, as it was not supposed that doses much smaller than necessary for the curative effect in guinea-pigs could be of value in the treatment of the human subject.

There were, however, conservative men among the profession who, appreciating the unmistakably favorable influence of the remedy upon the animal, and recognizing that, despite the disasters in many instances, it acted curatively in man also, looked for a safe method of application by reducing the doses to such as showed no toxic effect whatever, and who, under careful selection of cases, hoped to still take advantage of the curative properties. Their results justified their faith. For myself, I can say that I have so applied the remedy for three years and a half, and that I have every reason to be satisfied with the results I have obtained, while, with the exception of my first few weeks of experience, I have never observed a single instance, in over twenty thousand injections since made, where the remedy acted detrimentally or produced undesirable symptoms or discomfort in my patients.

Tuberculin was not all one could desire, but it was a help—indeed, an important one—and, never having had faith in panaceas, nor ever expecting that we should get them, I was glad of the addition to my resources, hoping that something better might come in the future.

In the meantime Professor Klebs and others undertook further experiments with the view of improving tuberculin by eliminating its toxic properties, the former devoting his entire time and energy to the subject.

Those interested will find a full account of the course of his investigations in his work on tuberculosis; my space will only permit me to mention that he found tuberculin to contain alkaloids soluble in alcohol; toxines, or toxalbumins, precipitated by sodic iodide of bismuth; while another albuminous substance, a sozalbumin, was found in the alcohol precipitate. All these substances were separated and tried upon guinea-pigs and other animals, and it was found that to the alkaloids were due the depressing and injurious effects upon the heart; to the toxalbumins, the fever, malaise, and inflammatory effects; while the sozalbumin was free from these properties. With the latter substance, now called antiphtisisin, Professor Klebs has cured guinea-pigs entirely, and kept others alive for long periods, while the control animals perished under the usual course and manifestations of tuberculosis and in the usual short periods of time.

In the human subject its application in doses up to several thousand times greater than permissible of tuberculin has produced no depressing effect upon the heart, no fever or inflammatory symptoms, and no other undesirable effects, while it has shown the same favorable curative influence as upon guinea-pigs, and under proportionally larger doses to a much greater degree than had been obtained from the use of tuberculin.

It still remains to be shown what the effects are of the substances contained in the bodies of the bacilli of tuberculosis, and highly interesting and probably important results may be looked for from this line of experimentation, which Professor Klebs began in the past year and is now pursuing further in the laboratory of this institution.

When these experiments are concluded we shall have each substance contained in tuberculin in an isolated form, and, so far as they are available for therapeutic purposes, we shall be able to use them separately or in various combinations, according to the nature and particular indication of a given case.

Antiphtisisin is unquestionably the germicidal part of tuberculin; it is obtained from the culture fluid from which the germs are previously filtered out; it is therefore a secretion and excretion product of the germ.

To answer Dr. Denison's question more directly, I would reply that tuberculin appears to be a complex substance containing toxines, toxalbumins, and germicides (sozalbumins), as well as alkaloids (ptomaines?).

As to its manufacture, it is very simple and as follows: The ripe culture (i.e., one which has reached its limitation of growth) is sterilized, then evaporated upon the water bath, reduced to one tenth the original amount, and then filtered.

In this connection a prevalent error should be corrected. At the time of its introduction it was erroneously believed that what was then called Koch's lymph, and subsequently tuberculin, was prepared under the control and auspices of the German Government, and was given to the world without profit, the amount paid, however, going into the hands of the government and not into those of Professor Koch and his associates. Professor Klebs informs me now that this has never been the case. The laboratory in the Lüneburger Strasse, in Berlin, where the remedy was prepared from the beginning, under the direction of Dr. Libbertz, was an entirely private enterprise of Professor Koch's, in which Professor Pfuhl, Dr. Libbertz, and possibly some others, had an interest, and to these gentlemen resulted the profits. Later the laboratory was transferred to the Farbwerecke of Meister Lucius and Bruning in Höchst-am-Main, where Dr. Libbertz has charge yet, and where the remedy is made for the benefit of those interested.

It is remarkable that the price for tuberculin of five
marks a cubic centimetre in Germany and two dollars a cubic centimetre in this country is still maintained, whereas Professor Klebs has reduced the price of the much more expensive purified preparation to one quarter of this amount, and contemplates still further reductions, as the facilities for its production are being increased and improved.

If we now consider the clinical aspect of tuberculin and its purified derivative (antiphthisin, Klebs), we can readily see that the great obstacle to the free use of the former for therapeutic purposes is the presence of the toxalbumins and alkaloids, these substances being highly poisonous in minute doses and producing the often described fever, malaise, nausea, diarrhoea, general aching, depression, and disturbances of the heart and circulation. To introduce considerable and distinctly effective quantities of the associated sozalbomin, or germicidal substance, we would have to give doses otherwise seriously detrimental, if not fatal, to the human subject.

Animals seem to have a greater tolerance for toxalbumins and alkaloids, and hence their greater tolerance for tuberculin to a degree that quick and curative effects followed its use in their treatment. In the human subject by very gradually increasing doses a certain tolerance can be established.

Under such gradual increase good results followed, especially in cases in which the disease was not very active nor following a rapid course; therefore in the early stage and in non-febrile advanced-stage cases we had the best results. These cases allowed of sufficient time to obtain a gradually increasing tolerance, but they also suffered acute exacerbations when the remedy was injudiciously pushed to larger doses. At best, the treatment had to be continued for a long time, and required such circumspection and watchfulness that I was never willing to administer tuberculin except to patients living in my own house and under my constant observation. I am still gratified with my results, and observe with much satisfaction that they have been quite uniformly maintained after the patients were discharged and had returned to their previous places of residence and mode of life. The remarkable absence of relapses would speak for a certain degree of immunity produced by the remedy.

In 1891 and 1892, when Professor Klebs first introduced a purified product of tuberculin under the name of tuberculocidin, I treated a series of cases with this substance and reported my results in the New York Medical Journal for 1892. I was then well convinced of the germicidal properties of tuberculocidin, but the price, three dollars a cubic centimetre, was practically prohibitive in view of the large doses required. The trial came to an abrupt termination by the destruction of my institution by fire in August, 1892.

In the early part of this year tuberculocidin was again made use of on two patients who proved entirely intolerant to even the minutest doses of tuberculin, and failed to show any improvement—one after three and the other after seven months’ residence in my institution. All other means having been exhausted, I resorted to tuberculocidin, and with very satisfactory results. Improvement became evident after only a few weeks’ use of the remedy, and both patients progressed so satisfactorily that other patients, observing the remarkable results, insisted upon being treated with it also. Both of these first patients made an entirely satisfactory recovery and have remained well. In addition to these two between fifty and sixty other patients have been treated, and since July antiphthisin has been used instead of tuberculocidin. The results obtained have been highly satisfactory, and will be reported in the future. At this time most of these patients are still under treatment, and with the exception of two, very far advanced and hopeless, who received the remedy at their own urgent request, we have witnessed improvement in various directions, clearly attributable to the antiphthisin in every case.

Three early-stage patients have been discharged apparently cured; at the time of their discharge all consolidation distinguishable by percussion had disappeared. The respiratory sounds were clearly vesicular, and the patients declared that they felt as well as ever.

Quite a number of more advanced-stage patients have also been allowed to return home, with instructions to return for further treatment if symptoms should again return, the disease appearing entirely arrested and the general health restored.

The observations of a favorable character which appear to me partly or entirely due to antiphthisin are as follows:

1. In all cases treated the fever became less as the doses were increased. In the earlier stages the fever subsided entirely and did not return. In the advanced stages, where septic and other complications were present, while the temperature diminished, it did not disappear entirely until the complications were also controlled.

2. In early-stage cases the cough and expectoration were favorably influenced at an early period of the treatment, and disappeared entirely as the treatment was continued. This is also true of night sweats.

3. The appetite and nutrition improved in proportion to the reduction of fever.

4. Degeneration (granular, club forms, and fragmentation) of the tubercle bacilli was constantly observed in all cases treated. The tubercle bacilli diminished steadily in number in the total quantity examined (one cubic millimetre homogeneous sputum), and finally disappeared entirely. In more advanced cases, where large cavities were present, while the degeneration and diminution in number were also observed, their entire disappearance from the globular sputum (from a cavity) has thus far only occurred in a few cases treated a longer time, but in non-globular sputum the degeneration and disappearance of the bacilli occurred the same as in early-stage cases.

* The longer continuance of tubercle bacilli in sputum from cavities Professor Klebs explains by the fact that the remedy can not reach them as readily there. In the cavity the tubercle bacilli grows more rapidly upon the solid, cheesy, degenerated walls, and upon the dead tissues lining them, which are cut off from the circulation. Only after such cavities have become clean and the walls have become vascular will the tubercle bacilli be accessible to germicidal influence through the blood.
In a considerable number of patients previous and repeated sputum examinations were available for comparison.

5. Remarkable changes have been observed upon physical examination, consisting in unmistakable clearing up of percussion dullness and return of a vesicular quality of respiration in the cleared up area. I can truthfully say that I have never seen such changes in so short a time. In several instances the previous dullness gave place to a deep, low notes, with evidences of emphysema. I have not failed in a single instance to observe such local improvement over more or less extensive areas, and explain this by the absorption of tubercular tissue and of inflammatory exudates from the aërii and alveoli of the lung, which is perhaps confirmed by the fact that the vital lung capacity was increased in reasonable proportion. Such patients, before the physical examination was made, stated that their breathing was freer, and that their shortness of breath upon exercise had certainly improved.

6. An almost uniform statement by patients of the benefit they themselves became aware of, especially as to easier and freer breathing, increased sense of strength and well-being, better appetite, less fever, less cough and expectoration, and better sleep.

7. The improvement observed by me in temperature, pulse, respiration, and by physical examination, and the subjective sense of improvement by the patients themselves, was obtained in comparatively short periods of time, usually beginning within the first three or four weeks, and such improvements were the more rapid when large doses were administered.

8. When the remedy was locally applied to tubercular ulcerations, the latter became clean and showed a tendency to heal, and in some cases treated for from several weeks to several months such ulcerations have healed and remain so to this time.

So far, then, my own experience confirms what Professor Klebs has alleged for antiphthisin as being specific and germicidal against the Bacillus tuberculosis, under the degeneration and disappearance of which the tubercular process undergoes retrogressive changes by the conversion of living tubercle cells into such as from which they have proliferated.

Such action, however, also indicates the limitation of the remedy. As it is a specific germicide, we can not expect it to control the conditions resulting from associated pathogenic germs of, for instance, the Streptococcus pyogenes, diplococcus, etc., nor can we expect to remove with it the symptoms and degenerative processes indirectly due to them, or to the tubercle bacillus. Antiphthisin must therefore not be expected to control septic processes, fatty or amyloid degeneration, nor reach the tubercle bacillus in dead tissues or localities not accessible to the circulation or to local applications.

These limitations must be clearly borne in mind in its application and in the expectation from its action.

In my endeavors for furthering the successful treatment of tuberculosis, and in my observations upon tuberculin and antiphthisin, I have ever been governed by the desire to find the truth. My convictions have justified me in inviting Professor Klebs to come to this country to aid me with his experience and advice. Since his arrival I have been able to induce him to associate himself with me in my work, with which he has been pleased to express his great satisfaction.

Tuberculin and antiphthisin will hereafter be produced here in our bacterio-therapeutical laboratory, which is now nearly ready for operation. Of this Professor Klebs will have exclusive charge, while he will also act as consulting physician to the sanitarium. The first experimental labor upon animals in the new laboratory will be in the direction of producing immunity to tubercular infection, and to determine in what part of the culture of the bacillus the immunity-producing substance is contained. Investigations will also be made as to the associated pathogenic germs in pulmonary tuberculosis, and especially in advanced cases with cavity. After their relation to the course and symptoms of the disease has been determined, efforts will be made to find in their culture products the proper remedy for their successful removal.

The results of these labors will be made known to the profession by frequent communications by Professor Klebs. For the present antiphthisin will not be given to the ordinary channels of trade. On the contrary, as it is appreciated that for the successful treatment of tuberculosis something more than the ability to give a hypodermic injection is required, a course will be offered in which full instruction will be given to members of the profession. The course will include bacteriology, pathology, physical diagnosis, and the general management and care as well as the specific treatment of tuberculosis.

To physicians of known ability in this field of labor, and to institutions where a scientific trial of the remedy is assured, antiphthisin will be furnished directly from the laboratory, and until its value is fully established it will not be given out in a general way; but special application for particular cases will be considered, and, so far as from the limited amount available it is possible to do so, the remedy will be furnished for such cases also.

As to the directions for the use of antiphthisin, it may be said that the same must be considered a germicidal product obtained from the culture fluid of the tubercule bacillus from which the toxalbumins and alkaloids have been removed by the method mentioned in a previous part of this paper. It is only recommended for use in the earlier stages of tuberculosis, and must not be expected to relieve complications, especially not those which are produced by other pathogenic germs, notably such as produce suppuration and septic fever. The remedy can only act upon living tubercular tissue and upon the tubercle bacilli which are within reach of the circulation. The more vascular the part the more rapid and distinct appears its specific effect. It must, however, be remembered that when a large number of tubercle bacilli are destroyed and a considerable quantity of tubercular tissue is being absorbed, toxic products the same as are contained in the unpurified culture fluids may thus be liberated within the organism which may give rise to aching, malaise, fever, and congestion of tubercular areas.
It is therefore best, except in the most urgent cases, to begin with the remedy in comparatively small doses, and to increase it gradually, thus avoiding effects which, although not at all dangerous, may give rise to alarm and anxiety both on the part of the physician using the remedy and of the patient.

Should such an effect nevertheless occur, the remedy may be intermittently for two or three days, until the effect has entirely subsided, to be then resumed with about half the previous dose administered, and the increase continued the same as before. Under the more cautious procedure the beginning dose for an adult is a tenth of one cubic centimetre of the ten-times concentrated solution, and this dose is increased by a tenth of a cubic centimetre a day until one cubic centimetre is reached. The latter may be repeated for several days, and the increase thereafter may be more rapid, by half a cubic centimetre at a time, repeating each such dose three or four times, or even a week, according to the effect produced.

Antiphthisin is non-poisonous and produces no symptoms unless such as may be caused by too rapid destruction of bacilli and absorption of their products. At present the maximum dose that has been reached is ten cubic centimetres a day, and when doses larger than one cubic centimetre are reached it is recommended to divide the dose, giving one half in the forenoon and the other half in the evening.

If the remedy produces local irritation at the point of injection, or when larger doses than one cubic centimetre are administered, the rectal method should be adopted, which consists in introducing the remedy, diluted with a small quantity of distilled water, with a small sterilized rectal syringe into the rectum. The great vascularity of the latter part causes more rapid absorption of the remedy, and observations thus far justify the belief that such administration is even more effective than the hypodermic method.

Intravenous injections are more effective still, and much smaller doses are required.

After a hundred cubic centimetres of the remedy have been used the question should be determined whether an intermission of some weeks or months should not be allowed, or the treatment stopped entirely. The entire and repeated absence of the tubercle bacilli in the expectoration, together with a corresponding amount of improvement, general and local, and the absence of all fever, would justify such a course.

The fever due to the tubercular processes will be found to disappear gradually when large doses of the remedy (from two to five cubic centimetres) are reached.

The present cost of antiphthisin is fifty cents a cubic centimetre, in phials of ten, fifty, and a hundred cubic centimetres, the amount for which, to save labor, must accompany the order. It is not intended to make the laboratory a source of personal gain; on the contrary, the object is to produce the remedy at so low a cost that the same will eventually be within the reach of the poor, which will be possible when the demand justifies its preparation upon a large scale.

The Wintah Sanitarium, January 5, 1895.
of the lesion, which was now in the stage of full development, M. Darier said, that in doubtful cases the microscope was of no assistance, and he added that the fact that the inguinal glands formed a compact mass, instead of being isolated, was not in favor of syphilis. To this M. Fournier replied that such a condition constituted the conglomerate bubo of Bassereau, which was occasionally seen in syphilis, and M. Besnier added that at that time he had three syphilitic patients under observation each of whom showed a conglomerate bubo of the epitrochlear region.

THE LION FROM A MEDICAL POINT OF VIEW.

The president of the Bristol Medico-chirurgical Society, A. J. Harrison, M.B., delivered before that society on October 10th a very interesting address founded on his experience in the gardens of the Clifton Zoological Society, with which he has been connected for many years. It appears in full in the current number of the Bristol Medico-chirurgical Journal. The experiences and observations mentioned in the address are not arranged in any formal anatomical, physiological, or pathological order, as the author states, but, fragmentary and disjointed as they are, they are exceedingly interesting. The first case mentioned is that of a lion, considered to be the finest lion in Europe at the time, and one that had always seemed in excellent health until a few months before his death. One morning he was found dead in his cage, and at the post-mortem examination it was ascertained that an enormous hemorrhage had taken place into the abdominal cavity, proceeding from the spleen, which organ, it was inferred, had been ruptured by the exertion of coitus. The splenic enlargement, says Dr. Harrison, seemed to have been caused by hyperemia and increase in the lymphatic and vascular elements, but as to the etiology, he can only speculate. "Are lions," he asks, "subject to malarious attacks? and had Hannibal been a victim in the days of his youth, in his native wilds—for he was forestbred—before the civilization of captivity had fallen upon him? He had been ill a couple of months or so before his death, when his breathing was affected. Did he have pneumonia then, with carination of the base of the right lung—or perhaps more probably a hemorrhage from an embolism—or are lions subject to splenic fever?"

Another lion, a fine creature, had become lame by reason of an ingrowing claw. The trouble went on from bad to worse until something had to be done, and it was decided to extract the claw. The use of chloroform, says Dr. Harrison, was out of the question, for attempts to give these animals anaesthetics have been worse than failures; so it was decided to resort to the "cramp-cage." With some difficulty the animal was got into this cage. "He didn't like his quarters," the account goes on to say, "and showed that even within the comparatively small dimensions he could turn round and so evade any efforts to get hold of his claw. Planks of deal, one foot broad by one and a half inches thick, were then put into the cage to limit the space. The animal was fairly furious before; but now came such a display of rage that no one who did not see it could imagine it. He fought for dear life, as he thought. Plank after plank was seized and ripped up like so much match-wood, and it seemed as if the iron bars and plates, strong as they were, would not contain the infuriated beast. His mouth bled, and he broke a tooth. Several of the keepers stood on the top of the cage to prevent it from being overturned, and some of the spectators took refuge by quietly withdrawing from the scene. At length, by putting in plank after plank, above and behind, the poor brute was brought to bay, and, to save himself from his very constrained position, pushed out his paws through the bars of the cage. 'Now's your time,' I said. Blundsen immediately seized the offending claw with a pair of strong carpenter's pincers; the grip was good. The animal helped in the operation by trying his best to get his paw free, and the claw came away. It had grown into the flesh at least half an inch, most likely more; and here I can show you the very thing. In half an hour afterward the creature had quite calmed down; he seemed then to have comprehended the rationale of the operation, and he gave me the conviction that if he had had to undergo a repetition he would have been a mild consenting party. The operation was completely and permanently successful."

The case of another lion is mentioned, one only four months and a half old, that was found dead in its cage. It had been ailing for three or four days; its breathing was very quick and it took no food, but simply lapped a little water. At the post-mortem examination the pericardium was found distended with a semi-purulent fluid, of the consistence of gruel, tinged somewhat with blood. Notwithstanding the tradition that in old times, when lions used to be kept in the Tower of London, the lion named Pompey is said to have lived there for seventy years, Dr. Harrison says he can not believe the story. He looks upon the lion, at least in captivity, as comparatively a short-lived animal, and gives various facts on which he founds this opinion. So decided is he that in the case of a lion that died at the age of sixteen years his conclusion was that the beast's death had been owing to senile decay. The death of a lioness, described as "rather rickety," is recorded as having taken place during parturition, from rupture of the right cornus of the uterus. The animal had been in labor for five days, and one cub had been born and the other was partly extruded into the vagina.

Dr. Harrison's address deals with pathological and physiological observations on various other animals, but the space at our disposal has allowed only of our referring to those of them that relate to lions.

MINOR PARAGRAPHS.

CONSUMPTION AS AN INFECTIOUS DISEASE.

While we earnestly hope that much good may come of the practice entered upon by our city board of health of presenting tuberculin before the public in the light of an infectious disease, we fear that hardship, if not actual suffering, may thereby become the lot of many a poor consumptive. Many sanitarians are urging the need of putting consumptives under the control
of sanitary officials. That course, it is to be feared, would result in such a popular dread of taking the infection as to realize the grim forecast made by Dr. H. Bennet, quoted in a vigorous article entitled The Consumption Scare, by Dr. Arthur Ransome, professor of public health in Owens College, published in the January number of the Medical Chronicle, of Manchester, England. Dr. Bennet says: "Social relations would be all but disorganized; a consumptive patient would be considered like a leper in olden days, one to be separated from his family, to be isolated, shut up. He would have to live months—nay, years—in a tent; his clothes should be destroyed, and whether he dies or recovers, the house which he has inhabited should be burned. It would, perhaps, be a charity to mankind to kill him at once, like an animal attacked with rabies; for, as the duration of the ordinary forms of phthisis may extend over years, during that period every time he breathed he would be filling the atmosphere with the germs of disease, wafted by the winds to be scattered far and near." To this Dr. Ransome adds: "Such is the logical sequel of the doctrine of the contagion of phthisis, carried to an extreme as it is now being carried by many, especially in Germany and France. The result of such teaching as I have described is already becoming apparent in many directions. Persons affected with almost any chest disease find it difficult to obtain places as domestic servants. The close ties of family affection are not always strong enough to induce relatives of consumptives to undertake what is considered to be the dangerous duty of nursing them. The sites for consumption hospitals are becoming as difficult to find as those for fever, and utterly unfounded reports as to the spread of the disease by such institutions are recklessly made, even by medical officers of health."

THE CHARTER OF THE NEW YORK HOSPITAL.

This ancient document, granted in 1771 by George III, of England, has been in great danger of irretrievable ruin, but fortunately it has now been restored and so cared for as practically to insure its perpetual preservation. Its dilapidation was so pronounced but lately that great apprehension was felt by the governors of the hospital lest some further accident might complete its destruction. Various New York professional restorers were asked to bring their art to bear upon it, but they all averred that its restoration was beyond their powers. It happened at last, however, that the excellent work of that sort done by Mr. Emery, of Tantum, Mass., came to the governors' knowledge, and he, having been invited to New York to inspect the document, expressed himself confident of his ability to perform the task of rescuing it from decay. He has succeeded admirably, and on Tuesday of this week the old charter, still showing signs of age, it is true, but smooth and perfectly legible, was hung in the hospital library. The charter embraces three large sheets of parchment, and the writing on each of them is close. The seal, about three inches across and half an inch thick, hung originally by a ribbon piercing the three sheets of parchment. As the charter is now displayed, the sheets are placed in proper order in a long frame, each in its own compartment and each compartment closed by a glass door which is kept locked. The seal, mounted on the top of the triocular frame, is ensheathed in a little revolving frame of its own, so that either of its sides may be inspected. The general appearance of the charter is exceedingly creditable to Mr. Emery's skill and judgment. If the courts will henceforth refrain from hurling duce tecum at it, the venerable document may last indefinitely.

ITEMS, ETC.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending January 29, 1895:

Behring's Diphtheria Antitoxine.—Last week we answered a correspondent to the effect that we had no trustworthy information that this antitoxine could be bought in this country at present. We have since been informed by Messrs. Schulze-Berge & Koechli, of No. 79 Murray Street, New York, that they are prepared to furnish it; indeed, their advertisement to that effect in our own columns would have so informed us had we not overlooked it.

Harvard Medical Society of New York City.—At the annual meeting, held on January 20th at Harvard House, the following officers were elected for 1895: President, Dr. Dillon Brown; vice-president, Dr. Charles L. Gibson; secretary, Dr. Theodore Dunham; treasurer, Dr. George E. Brewer.

The Buffalo Academy of Medicine.—Meetings of the Sections in Surgery, in Medicine, in Pathology, and in Gynecology and Obstetrics are held monthly, on successive Tuesdays, at the academy's rooms, Market Arcade, at 8.30 p.m. General meetings of the academy are held in September, December, March, and June.

A Curious Example of Frenchified English is to be found in the January number of the Archives de neurologie, in an abstract of an article that appeared in the American Journal of Insanity. Such names as Dakota du Sud, Virginie de l'Ouest, and Nouveau Jersey are not particularly remarkable, but when it comes to Nouveau Foundland the matter becomes a trifle comical.

The Late Dr. Loomis's Will.—It is announced that by the will of the late Dr. Alfred L. Loomis the Loomis Laboratory is to receive the sum of $25,000, and the New York Academy of Medicine the sum of $10,000, the latter to be known as the Loomis Entertainment Fund, a fund that has been much needed by the academy.

The Richmond, Va., Academy of Medicine and Surgery,—The next meeting will be held on the evening of Tuesday, the 5th inst. A discussion on the treatment of gout and the uric-acid diathesis will be opened by Dr. Landon B. Edwards.

Change of Address.—Dr. Carter S. Cole, to No. 101 West Seventy-fourth Street, New York.

Society Meetings for the Coming Week:

MONDAY, February 4th: New York Academy of Sciences (Section in Biology); Morrisania Medical Society, New York (private); German Medical Society of the City of New York; Brooklyn Anatomical and Surgical Society (private); Corning, N. Y., Academy of Medicine; Utica, N. Y., Medical Library Association; Boston Society for Medical Observation; St. Albans, Vt., Medical Association; Providence, R. I., Medical Association; Hartford, Conn., Medical Society; South Pittsburg, Pa., Medical Society; Chicago Medical Society.
TO THE EDITOR.

POTASSIUM PERMANGANATE AS AN ANTIDOTE.

335 Boulevard, West, New York, January 15, 1895.

To the Editor of the New York Medical Journal:

Sir: In the Annual of the Universal Medical Sciences for 1894, under the heading Phosphorus, it is stated that the best antidote in phosphorus poisoning is permanganate of potassium. Having made with the latter extensive studies for the past two years, I have become quite familiar with its mode of reaction toward different organic and inorganic bodies, and I am obliged to say that it has absolutely no antidotal virtues per se against phosphorus, for not even contact of these two substances lasting sixteen hours will result in any mutual reaction. I have traced the above-mentioned statement that the permanganate is the best antidote to phosphorus to the original article on the subject embodying the experiments made by Dr. Antal, of Budapest. The author says: "My experiments in regard to phosphorus poisoning were made at first on rabbits; these animals are not suitable for such researches, for their stomachs contain food even after a day's fast, and these matters reduce the permanganate before the latter has time to act upon phosphorus." Thus we see that Dr. Antal himself makes it a condition sine qua non that the animal's stomach must be empty if permanganate is to have any effect upon phosphorus; no wonder that this is the case in view of the fact that the permanganate has practically no effect at all upon phosphorus, as it requires such a long time for any chemical reaction to take place between the two substances. In connection with this it might be interesting to mention that peroxide of hydrogen does not oxidize phosphorus at all, although the latter is so readily oxidized by the atmospheric air (see Dr. Kastenbaine's article in the Louisville Medical Monthly for July). In fact, permanganate of potassium and peroxide of hydrogen, far from being antitoxics to phosphorus, constitute a chemical curiosity in regard to their behavior to phosphorus, which is oxidized so remarkably slowly by these powerful and ready yielders of oxygen. It is no wonder that the author of the article in the Annual of the Medical Sciences advises the administration of the potassium salt before the phosphorus becomes absorbed, since "vomiting will generally prevent a chemical reaction." Thus we have two conditions which are requisite in order that the permanganate shall have any antidotal action to phosphorus: First, the patient's stomach must contain only phosphorus and no organic matter; second, the patient must be forbidden to vomit the permanganate solution which has been administered.

Allow me to cite you one of Dr. Antal's experiments. This author soaked a thousand phosphorus matches in a litre of milk for twenty-four hours. In his first experiment he gave to a dog weighing twenty-five kilograms one hundred and eighty cubic centimetres (six ounces) of the poisonous milk, and then he administered to the animal two litres—i.e., half a gallon—of a 0.15-per-cent. solution of permanganate containing forty-five grains of this substance. The dog survived, but I should think that half a gallon and six ounces of liquid pumped into a fifty-pound animal's stomach would be sufficient to flush and wash out his whole digestive tract. Besides, this enormous quantity of liquid, forty-five grains of permanganate, after having been reduced to hydrated manganese dioxide, forms an immense quantity of a muddy substance which would carry off everything before it and thus would act as a mechanical antidote just as animal charcoal does. The other experiments are similar—that is, very large amounts of liquid and permanganate and the poison given on an empty stomach.

The first condition for permanganate of potassium to act as an antidote to any toxic substance is that it should act instantaneously upon the poison, else it would be unreasonable to administer it, not knowing the amount of organic material present in the patient's stomach at a given moment. The simplest test will convince anybody that atropine, hyoscymine, hyoscine, cocaine, aconitine, veratrine, pilocarpine, muscarine, and caffeine are not decomposed by potassium permanganate, even after having been in contact with the latter for many hours; furthermore, that the permanganate will give up its oxygen much quicker to albuminuous matter than to strychnine, oxalic acid, colchicum preparations, or hydrocyanic acid. On the other hand, the potassium salt of permanganic acid instantane-
FEES FOR LIFE-INSURANCE EXAMINATIONS.

BUFFALO, N. Y., January 26, 1886.

To the Editor of the New York Medical Journal:

SIR: The medical examiners of the New York Life Insurance Company have received an insulting letter which begins as follows:

"DEAR DOCTOR: We have just received instructions from the president to make an arrangement with our examiners in large cities by which the fee for medical examinations shall hereafter be three ($3) instead of five ($5) dollars. The considerations which have led up to this conclusion are that the company has in the past placed in your hands a considerable amount of business, and that, should you accept the proposed terms, it is its intention to continue to give you as much business, if not more, than heretofore. The company feels that it stands in the same relation toward you that a patient stands toward his attending physician. A physician charges five ($5) dollars a visit for occasional visits, when he would hardly feel warranted in charging so large a fee for regular medical services extending over a considerable length of time. In the latter case it certainly is the uniform custom among physicians in making out their bills to make considerable reductions from the fee for a single visit on account of the number of those visits."

The letter continues, saying in polite language that you may accept the new arrangement or resign, and is signed by one of the assistant medical directors.

It is evident that the management is trying to make a good showing in the reduction of expenses and has taken a very poor method of accomplishing its object. Only a third or fourth rate man would make examinations at the absurd fee that they suggest. Instead of reducing the fees for medical examiners it would be much better to increase them to that extent that it would be worth the while of thoroughly competent men to make careful and complete examinations. A truly thorough examination would require two days—a half hour for the physical examination and another half hour (twenty-four hours later) for the complete examination of the twenty-four hours' excretion of urine.

A good example of the incompleteness of the ordinary life-insurance examination came under my observation only last week. A gentleman had been accepted for a large amount of insurance by one of the large New York companies. A single sample of his urine had been examined. Three days later he consulted me, as he was not feeling very well. It is not necessary to go into details, but a careful physical examination of the chest revealed a heart which had no valvular murmurs, it is true, but whose first sound was to its second as about 1 to 2 instead of 5 to 3, and had lost its muscular tone entirely. The twenty-four hours' urine revealed no albumin or sugar, but the amount of urine and of urea were about half what they should have been.

The examination made in this case was certainly a five-dollar, probably a ten-dollar examination.

If that is the sort of work that the companies are getting at their present fees, what can they expect if they reduce the fee to the paltry sum of three dollars?

The following letter which I have sent to the company explains my position in the matter, and I trust you will publish it entire:

"New York Life Insurance Company,

A. Huntington, M. D., Medical Director.

DEAR DOCTOR: Permit me to announce my resignation as a medical examiner for the New York Life Insurance Company. At the same time permit me to say that I should think that you, as a medical man, would be ashamed to countenance any such letter as has just been sent out by Dr. Rogers, assistant medical director. You know perfectly well that no physician of any standing whatever would give even to a member of one of his regular families an examination, such as is required by a life insurance company, for less than ten dollars, and that examinations are made for insurance companies at the five-dollar rate because of the amount of business they are supposed to send to the examiner.

"Long ago I tendered my resignation to your company because, as I said at the time, it was not worth my while to go to an applicant's office or house to examine him for less than ten dollars, but that if the agent cared to bring one to my office during office hours, I would examine him at the five-dollar rate.

"At that time you asked me, as a favor, to allow my name to remain among those of your examiners, and I did so. Now, however, the mere fact that the medical department should allow such a proposition as has just been made to receive its sanction renders it impossible that I should allow my name to remain any longer as one of its medical examiners."

DELANEY ROCHESTER, M. D.

Proceedings of Societies.

AMERICAN ASSOCIATION OF GENITO-URINARY SURGEONS.

Eighth Annual Meeting, held in Washington, May 29, 30 and 31, and June 1, 1894.

The President, Dr. GEORGE CHISMORE, of San Francisco, in the Chair.

(Continued from vol. 12, page 327.)

Exfoliation of the Mucous and Submucous Coats of the Bladder, Preceded by Renal and Vesical Calculus.—Dr. ALEXANDER W. STEIN, of New York, read a paper on this subject. He first referred to the fact that exfoliations of the mucous membrane might occur from the uterus, vagina, larynx, and other mucous tracts. That complete exfoliation of the mucous membrane of the bladder might occur had been repeatedly denying, and that quite recently, although there were at least fifty cases of this kind on record. Some of the text-books, it was true, mentioned a diapheritic and erogenous cystitis, but with these conditions the cases collated had nothing in common. Not only had the entire mucous membrane exfoliated en masse, but portions of the muscular coat had come away as well. In one case the entire mucous coat had been shed in the form of a sac, and after an interval of some days a portion of the muscular tunic had been cast off separately. The real question at issue, therefore, was not whether exfoliation of the bladder occurred, but how it occurred. Reasoning from analogy, we inferred that when a mucous membrane was subjected to prolonged or intense irritation, as after the employment of powerful urethral injections or the presence of ammonical urine in the bladder, the vitality of the epithelium became
Among 151 cases that had been reported, forty-five had been in females and forty in males. In all of the former the retention had been due to a retroverted gravid uterus, or else the pressure of the child's head in prolonged labor. The cast-off shreds usually had a gritty feel and were covered with a phosphatic deposit. The prognosis in women was good. The expelled membranes were often expelled per urethram, en masse, and so ended the trouble. Of the forty-five women, nine had died, and the fatal termination had not been altogether attributable to the vesical lesion. In men the reverse was the case. Two of the five patients had died. The prognosis in men was not so good, because the conditions which gave rise to the exfoliation were in themselves grave, independent of the bladder trouble. Complete recovery occurred in some of the most un promising cases, but there was apt to remain for a time a disturbance of co-ordination between the retentive and the expansive forces of the bladder. The author then gave the history of a case of this kind that had come under his observation, and exhibited some of the shreds passed by the patient.

A Plea for the Excision of the Initial Lesion of Syphilis.—A paper on this subject by Dr. Edwin E. King, of Toronto, Canada, was read by the secretary. The author stated that, while the specific microbe of syphilis had not yet been isolated, it was almost beyond doubt that the disease was caused by a specific germ. In all gum diseases there was a period of incubation of variable length. In a good many the effect of the germ was self-limited, while in others it was continuous. That mild cases of these diseases occurred proved either that a smaller dose of the germ had been administered, or that the soil was not properly suitable for its growth, or that both these conditions existed together. In all cases we had a period of incubation, one of exacerbation, and one of remission. The intensity of secondary syphilis had been held to be in direct proportion to the extent of the initial lesion; this the author said he had corroborated, and he had further demonstrated clearly to himself that it was also in direct proportion to the time that the initial lesion had existed. He did not think it was possible by any known means to abort syphilis once the germ in sufficient quantity had entered the general system, but that the course of the disease could be greatly modified by limiting the amount of the poison which entered the economy. Excision had been useful in other diseases where fatal results followed the introduction of a poison when neglected—for instance, death from rickets and from the bite of a cobra had been prevented by free and early excision. So with syphilis, if it was possible to see the lesion during the first few hours of its existence and to excise it at once, the disease might be aborted. Even with the ameliorating results, the patients should not be allowed to be careless about internal treatment.

Among the cases reported in which the author had performed early excision of the initial lesion was the following: A man had noticed a slight crack on the free border of the pro- puse. Fifteen days previously he had had intercourse with a woman of the town who "had had a skin disease on her body." This woman, on examination, had been found to be suffering from a syphilitic eruption and from mucous patches on the vulva. The lesion on the man's penis had been immediately excised under antiseptic precautions and the edges of the wound had been brought together with fine silk. Since that time (June, 1893) he had presented no further symptoms of syphilis. In six other cases reported by the author the history and results had been much the same.

Epithelioma of the Penis.—Dr. Edward Martin, of Philadelphia, read a paper on this subject. After detailing the histo-
much enlarged in all directions in the shape of a distended leech, hot, brawny, and exquisitely tender. Deformation was very painful and perhaps complicated with rectal tenesmus, and might be attended with vesical spasm; sleep was heavy and refreshing, and often during the night painful erections, perhaps bloody, might add to the patient's sufferings. In a few days the swelling might still further increase, and then moderate fluctuation might be felt.

The chronic form might result from the non-occurrence of resolution in the acute affection, and in this form the clinical history was tolerably clear and striking. But in the majority of cases it began as a low-grade inflammatory process in persons, particularly of neurotic type, who might suffer from chronic or subacute posterior urethritis or chronic prostatitis, in confirmed masturbators, in those given to excessive venery, and in alcoholics.

In the acute form of this trouble resolution usually took place. In the chronic form amelioration and cure might be obtained. In some cases, however, the morbid process went on to the formation of large tumors, which required operative interference.

When it was recognized in the acute stage, gonocystitis was to be treated on the general principles which governed the management of all phlegmonae of the genital and urinary organs. A good plan was to apply a large number of leeches upon the perineum and the margin of the anus. Injections of cold water might be used, and the rectum might be packed with ice if the procedure was pleasant to the patient. Opium in suppositories, elixirs, and salines cathartics might be administered as required. Should an abscess form, it might be reached by means of a long incision in the perineum, just anterior to the anus. The resulting cavity should be treated on general surgical principles. When the abscess was not large, but well defined, it could be aspirated through the rectum. In more acute and extensive abscesses, free incision through the rectal wall, followed by careful antisepsic packing, had been recommended.

In the treatment of the chronic form, in which we might find distended, pouchy vesicles, much stress had recently been laid by Dr. E. Fuller upon what he termed stripping or milking the vesicles with the finger tip, which was inserted into the rectum. The author said it was no easy matter in many cases to reach the vesicles with the finger, and to clearly define their size and shape. Moreover, the seminal vesicles were made up of blind-ended tubes or diverticula, and for anatomical reasons it would clearly be seen that the utmost that could be accomplished by stripping or milking a vesicle was to act upon about a quarter of its whole structure. The author said he had no doubt that the amputation of the vas deferens which was so common near the prostate had often been mistaken for enlargement of the seminal vesicles.

Dr. Gardner W. Allen said that in the cases that had come under his observation the symptoms had not been characteristic, and a diagnosis could be made only by a rectal examination. In these cases he thought he had succeeded in reducing the size of the organs by pressure with the finger tip exerted through the rectum.

Dr. Martin expressed the opinion that in comparatively few cases of epididymitis was there any evidence of swelling of the seminal vesicles. In healthy men he had not been able to locate the vesicles at all.

Dr. George E. Brewer, of New York, mentioned frequent ejaculation on very slight provocation as a symptom of the chronic form. In spite of Dr. Taylor's demonstration, he thought it possible to express some of the contents of these overdistended sacs by pressure through the rectum.

Dr. James R. Hayden, of New York, said that his attempts at milking or stripping the seminal vesicles had proved very unsatisfactory.

Dr. Bangs referred to the difficulty he had had in outlining the seminal vesicles, excepting in chronic cases. In some instances, by making pressure through the rectum, he had been able to express a fluid which had contained spermatic elements; whether this had come from the ampullated part of the vas or from the vesicles themselves he did not know.

Dr. Robert F. Weihe, of New York, described a method of opening abscesses of the seminal vesicles through the perineum. He stated that in a number of instances he had removed the vesicles for tubercular disease, together with the testis and vas deferens.

Dr. Belfield called attention to the fact that the signs peculiar, when distended, formed a swelling in the region of the seminal vesicles.

Dr. Butson said that chronic inflammation of the vesicles might be mistaken for tubercular inflammation.

Dr. Taylor said that when the seminal vesicles were inflamed and distended, severe pressure in that region was apt to produce rupture of their walls. In the majority of cases it was probably the ampulla that was manipulated through the rectum, and not the vesicles themselves.

(To be continued.)

Book Notices.

This posthumous work of one of the most learned, brilliant, and respected of English physicians will be welcomed by all who had learned to appreciate his learning, diagnostic acumen, and great clinical acumen, as well as his wide culture and amiability.

It passes into the group of the British medical classics with such companions as the works of Sir Thomas Watson, Sir Dominie Corrigan, Graves, and Walsh, and the illustrative productions of Carswell and Silson.

The plates depicting the gross pathological anatomy of the various forms of pulmonary fibrosis are very skillfully drawn, and colored with such a fine taste as to give the reader an idea of the appearances which can scarcely fail to give him insight in the post-mortem examination of such a case.

The clinical pictures, too, are, some of them, comparable to those of Dr. Graves, who, in the writer's estimation, was facile princeps in the art of skillful delineation of symptomatic groups and the indication of their diagnostic bearings.

The introductory is one of the neatest, most skillfully arranged, and most pleasingly enunciated of all the preliminary historical summaries with which we are acquainted. Written by the collaborators, it gives us a brief, concise, but accurate account of the development of our knowledge of the subject. Beginning with Bayle and Laennec, and progressively stating and interpreting the views of Audral, Chomel, Stokes, Corrigan, Brunsais, Graves, Addison, Girrous, Rokitansky, and Ilasse, it brings us to Handfield Jones and Hughes Bennett. Dr. Sutton, whose name is now so frequently associated with
BOOK NOTICES.

that of Sir William Gull on account of their joint labors on arterio-capillary fibrosis, advanced the view that the fibroid diseases of the lung were local manifestations of a constitutional degenerative condition, the cæseous nodules being due to what Virchow would call a necrobiosis change arising from malnutrition. And so the discussion continued until the lamented Sir Andrew Clark, in 1868, reported a single case of what we should denominate fibroid phthisis. There are evidences here of an imperfect faculty of accurate observation, as he remarks, for instance, that there were "signs of consolidation and excavation at the left base, with contraction of the chest, the heart being displaced upward and outward, and uncovered." But the description of the post-mortem changes scarcely bears this out. "The left lung was contracted, universally adherent, and the pleura much thickened, presenting both old and recent adhesions. Fibroid septa were found traversing the lung in all directions, but chiefly following the course of the bronchi and blood-vessels, and running from the thickened pleura," etc. This, with a few further remarks, bears evidence of careful examination, but the reviewer would not regard them as conditions which would in any but a small proportion of cases occasion the physical signs of consolidation and excavation. It has been his experience, which includes many cases in which the examination during life has been compared with the post-mortem appearances, that a lung in the condition described has, as a rule, almost an absence of respiratory sounds, except on very vigorous breathing, when some faint bronchial breathing was to be heard; was dull, but not flat, on percussion, and that the vocal resonance was slight. We must admit, however, that these signs, taken together with the others mentioned, would be sufficient for an expert like Sir Andrew Clark.

A notable omission is the failure to speak of the clubbed fingers, which are so highly developed in this condition that they are often noticed by non-professional persons.

It is a question, too, whether Sir Andrew did not lay too much stress on the cardiac displacement. While contraction of the thorax, especially when it is unilateral, would seem necessarily to displace the heart, yet it not infrequently occurs that the accompanying pericarditis fixes the organ and prevents the dislocation.

But these slight criticisms, if justified, indicate only a few small spots on the sun.

This most interesting historical account of a new disease reviews next the work of Wilson Fox, of Clarkson Bastian, and of Jürgensen, who did so much to make popular the term interstitial pneumonia.

He and Cohnheim also popularized the rational explanation of bronchiectasis.

Douglas Powell and Walshe are given their due, and then we are introduced to the man who, the reviewer believes, will outrank them all in the annals of fame—a man of prodigious learning, of seemingly infallible judgment, of wonderful clinical skill, who was taken off before his time and left his book, the monumental labor of his life, to which he had devoted his best powers for ten years, to be finished by his friend Dr. Pye Smith. Hilton Fargue had, indeed, a worthy editor for his great work, but it was a sorrowful task, no doubt.

With our limited space we have thought it better to give a simple description of the introductory part of the book. The illustrations are beautiful, and as a whole this small volume makes a capital monument to Sir Andrew Clark. Its readers should feel greatly indebted to his collaborators and editors.

The author first reviews the ontology and phylogeny of the breast, and describes the morphology and secretory anomalies of these glands. He then refers to unilateral and bilateral amenia, to micromastia, to athelia, and to atrophomastia. As regards the last-named, he holds that when the essential sexual organs are removed early in life, before the secondary sexual characteristics have become thoroughly well established, these latter remain undeveloped, though when the removal of these organs is deferred until the secondary sexual characteristics have become well established, the latter generally persist. This view, of course, is nothing new.

The author considers that the fact that additional mammary structures in polymastia do not develop in any but certain definite positions, that correspond with those occupied normally by the glands of polymastic animals, warrants us in attributing their occurrence to reversion. From the cases of polymastia reported he concludes that our remote progenitors had at least seven pairs of mammary on the ventral aspect of the trunk; of the six lost pairs, three were situated above and external to, and three below and internal to, the present pair. To carry out this reasoning a little further, it would seem from the fact that among the recorded cases of mammary verrucosae are a number of instances of median breast that the author's heptamastic woman was the specialized descendant of a polymastic female who was correctly depicted in the ancient statue of Diana of Ephesus.

Hypertrophy of the breasts he considers to be either diffuse or circumscribed, and generally associated with menstrual deficiencies and pregnancy. Gynaecomastia is attributed to the principle of correlated variability and the doctrine of the latent hermaphroditism of every human being.

Pathological neoplastic processes of the breast are explained as aberrant repetitions of normal developmental processes. The author considers that the evidence is against a specific cancer microbe. The term cancer is restricted to a malignant neoplasm of epithelial origin. The morphology of the primary neoplasm in mammary cancer, and the lymphatic or the general dissemination subsequent thereto, are described with a completeness that leaves nothing to be desired.

From an analysis of a large number of cases of cancer affecting all parts of the body, the author concludes that the greater liability of women to cancer is not the outcome of any general constitutional condition correlated with sex, but is due to biological peculiarities inherent in the reproductive organs themselves. He finds that the average age of women at the onset of mammary cancer is forty-eight years, whereas for uterine cancer it is forty-four.

After detailing the geographical pathology and the heredity features of cancer, the author concludes that if unchecked that disease will ere long become one of the commonest diseases of humanity. He concludes that most cancer patients are the surviving members of tubercular families, and, as we know that tuberculosis is increasing, there may be some ground for this assumption.

While admitting that it is possible for benign neoplasms to take on malignant characters late in life, the author does not believe that such neoplasms are specially prone to develop malignant disease.

Regarding the benefit of operative procedures, the author has found that complete cures may be expected after thorough operations for cancer of the breast in at least fifteen per cent. of all cases, while mammary cancer left to itself inevitably ends in death.
Attention is directed to the fact that under the term villous cancer two perfectly distinct neoplasms have been included—non-malignant villous papilloma and malignant tubular cancer. An interesting chapter is that on the rare cancer of the mammary integument.

While the author finds that cancer of the breast in men may originate either from the acini, from the ducts, or from the integument, yet cylinder-celled duct cancers are more frequent than among women.

An analysis of 13,824 primary neoplasms shows that there were 1,081 sarcomata, and of these only 99—5 in men and 94 in women—affected the breast. Of 2,397 convulsive neoplasms of the breast in women, 77-7 per cent. were cancers, while 3-9 per cent. were sarcomata, an evidence of the greater stability of the parablastic as compared with the archiblastic elements of the gland. In the series referred to there were but two examples of myxoma.

Fibroma, fibro-adenoma, lipoma, chondroma, osteoma, angio-oma, xeroderma, and cysts of the breasts in the two sexes are given due consideration.

The chapter on inflammation and suppuration is an interesting one.

The author maintains, on the evidence afforded by recent investigations, that all forms of mammary inflammation, with the possible exception of erysipelas, are consequent on the presence of irritant substances of microbial origin within the ducts.

The author has studied his topic with great care and thoroughness, and it is not too much to say that there is no monograph on the subject of diseases of the breast that is superior to this.

This work gives a very comprehensive description of the atrophy and regeneration of the elastic tissue of the skin under various pathological conditions. The authors find that the elastic tissue disappears in all inflammations and neoplastic formations in proportion to the intensity of the pathological process. Inflammation is particularly inimical to the elastic tissue. Degeneration is manifested by a loss of the staining power and a thickening of the fiber with eventual molecular degeneration.

The work is illustrated with photomicrographs of sections of syphilitic papules, of papulo-squamous eczema, of chondroma of lepromatous, and of molluscum contagiosum.

This study is an interesting contribution to the scanty literature of the subject.

The result of the second revision of Dr. Bartley's work is to give us a most excellent text-book upon medical chemistry. It is written, as the author frankly states, for the student, and is largely a compilation, but it is certainly a good one. The addition to this edition of a chapter on physiological and clinical chemistry, "which deals with the chemistry of nutrition, foods, digestion, milk, and the urino," is one of the best features of the volume.

The many contributions that the author of this work has made to our scientific literature have made his name as familiar among Americans as among Europeans.

In this volume Professor Gautier describes the cell and the rôle of its various parts, and shows that organism in action. He then reviews the phenomena of assimilation and of disassimilation, and he concludes that the direct products of the disassimilation of protein matters result fundamentally from a splitting up of elements and not from oxidation. These products are peptones, toxines, and toxalbumins, diastatic fermentations, amide bodies, leucornaines, and ptotamines. He divides leucornaines into four classes—nutrinie, creatinie, xantbic, and undetermined leucornaines.

The function that preserves the cell and makes it a complete being is fully analyzed in this volume, which modifies the generally accepted physiological theories decidedly.

The Jewish Method of Slaughter compared with Other Methods from the Humanitarian, Hygienic, and Economic Points of View. By J. A. Dimeo, M.D., Physician to the Alexander Hospital, St. Petersburg, etc. Translated from the German with the Author's Amendments. Published by the Trustees of the Late J. A. Franklin. London: Kegan Paul, Trench, Trübner & Co., 1894. Pp. xiv—111.

The author of this work presents good evidence that the Jewish method of slaughter, the "shecheta," is a humane method because loss of consciousness and insensibility take place more quickly with it than with other methods of killing animals. He states that the cut with the extremely sharp and smooth-edged knife is entirely painless, as there are few sensitive nerves encountered in the neck.

This method has an advantage from the hygienic point of view, because there is a copious and rapid escape of blood, and the epileptoid convulsions that appear toward the end of the bleeding cause the development of lacteic acid in the body of the slaughtered animal, and that combines with potassium phosphate and transforms it into potassium tartrate and dihydrogen potassium phosphate. This latter salt impedes the development of micro-organisms and the formation of cadaveric alkaloids. The author considers that the convulsions render the meat tenderer.

The book seems to be the outcome of a report of a German society for the protection of animals that condemned the Jewish method of killing as barbarous.

This is the first volume of a series that the author intends to publish for the purpose of presenting the results of his surgical work from the time he began his service in the Pitié hospital, in 1879, up to the present day. The first chapters of the volume represent his practice during his early days, and as time advanced he adopted newer or better methods, their results are to be outlined in the later volumes.

This volume is devoted exclusively to the statistics of surgical injuries of the lower extremities. More or less extended observations are given of 2,494 traumatic lesions in which there were 2,364 cases of recovery or improvement and 40 deaths, and of 2,345 organic affections, in which there were 2,274 cases
of recovery or improvement and 71 deaths. In 1,926 operations on the soft parts or the bones of the lower extremities there were 56 deaths.

The volume is an interesting record of surgical achievement,

This is the first fasciculus of the first volume of a work on practice that is intended to be a concise manual for students and practitioners.

The first volume is devoted to infectious diseases, and in this fasciculus there is a satisfactory résumé of the history, etiology, pathology, symptoms, and treatment of measles and scarlet fever. From the references in the text it is apparent that the author has studied his topics in the medical literature of the world, and the volume is likely to prove a useful contribution to Italian medical literature.

A NEW PHOROMETER TABLE-BRACKET.

By ISAAC C. SOULÉ, Ph. D., M.D., FREEPORT, ILL.

When in March of the present year Dr. J. F. Herbert gave to the profession the description of his new adjustable phorometric bracket, I thought that he had accomplished that for which I had been striving for the past two or three years, to wit, the elimination of some of the trials to which the oculist (and I might say his patient as well) is every day subjected. It is not necessary to enumerate this list, so often gone over; every oculist is perfectly familiar with its varied forms; so I will not take up time, but hasten on to the immediate subject of this short paper.

First, before giving the description of my own instrument, allow me to refer briefly to that of Dr. Herbert.

This is truly an excellent instrument, a long step forward in the right direction, and while it obviates the trouble we at times have in adjusting the trial frame to the patient's face, on account of lack of symmetry, removes the weight of which the patient so frequently complains, secures greater rigidity, and otherwise gives us numerous advantages over the frame, it seems to me, from a trial of it, that the doctor has failed to accomplish a part of his desideratum, and that the bracket has some disadvantages as great as its advantages. After first satisfying myself of this, I determined to complete my own instrument, hoping to accomplish more fully that for which Dr. Herbert was striving.

I call my instrument an adjustable phorometric table-bracket, as by so doing its general character is at once made apparent.

Fastened to the edge of a table (which for the sake of rigidity should be screwed firmly to the floor) is the combination clamp A, extending upward, from which is a bar B, curved at its upper extremity, forming the main support for the instrument.

The lower end of this bar B fits into a double socket in A and has a deep, fast thread upon which works a coarse knurled nut C, by means of which B is easily and quickly raised and lowered.

Thus adjusting the instrument to different heights, the upper socket in A is slit and has working in it a binding screw D, which converts it into a strong clamp, holding B perfectly secure and rigid at any angle or elevation. Fastened to the upper curved end of B are two heavy brass plates; one, E, is moveable and is the base plate to which is securely fastened at an angle of forty degrees a plate or bar G, upon which slide the lens carriers. These lens carriers a a are two broad, strong, supports, so fastened to their supporting bars as to have a large bearing in that way assuring to them rigidity and preventing a binding in approximation and separation, which is accom-
plished by a right and left threaded rod $b$. Working in the
lens carriers $a$ are the revolving cells $c$, which have cut on
their posterior edges a deep gear into which works a worm, $d$, $d$,
by means of which they may be revolved in either direction.
Attached to the carriers $a$ are four cells, $e e e e$, those in

front capable of containing two lenses, those in rear three, and
slotted so as to permit of the revolving of a lens. Secured
fastened to the bar $G$ (which supports the lens-carriers), at
either end are upright supports, $H H$, to one of which the
phorometric slide is so attached as to permit of its being
swung to one side out of the way; the other one acting merely
as a support to the other end, holding the slide always parallel
with the supporting plate and lens holders. Keyed to the
supporting bar $B$ is another plate, $F$, in which works a thumbscrew, $f$, by means of which the instrument is leveled. $I$ is the
level on base plate $E$. Attached to the supporting bar $B$ by
means of set screws is a very strong but light bracket entirely
independent of that portion of the instrument containing pho-
rometer and lenses. In the end of this bracket is the chin rest
$J$, and to the side of it is attached the bracket supporting the
forehead rest. The chin rest $J$ is elevated and depressed by
means of a rack and pinion movement, $K$, and held at any de-
sired position by a thumb-screw.

In as few words as possible I shall endeavor to point out the
advantages alleged for this instrument:

1. It is rigid. Dr. Herbert's is not: a slight stroke, such as
would result from the putting in place or removal of a lens,
being sufficient to cause it to vibrate from a minute to a minute
and a half.

2. It is convenient. By loosening binding screw $D$, the in-
strument may be swung around over the table out of harm's
way. The patient is seated at a convenient distance from the
table, and the instrument is swung out in place (it projects nine
inches from the edge of the table), and raised or lowered, as
occasion requires, by means of nut $C$, thus preventing the neces-
sity of having the patient get up one or more times to raise or
lower a stool.

3. The lenses are nearer the ideal position. By placing the
lens-carriers at an angle of forty degrees, you get the lens in
rear cells at the nodal point or nearly so; your patient is not
hampered by anything in getting close to the instrument, and
has plenty of room for his nose and breathing.

4. The patient's head is securely and comfortably held in
position by chin- and forehead-rests.

5. By means of the rack-and-pinion movement of the chin
rest, the head may quickly be raised or lowered to get the pupils
in the vertical center of the lenses.

6. The mechanism of the revolving cells is more perfect.
The construction of the revolving cells will at once be seen.
Revolving as they do within a complete ring, one half of the
cell screwing into the other, makes them at once secure, and
renders it impossible for them to catch or bind. The gear on
the posterior edge is cut deep, so there will be no danger of
slipping or jumping. The worm is so pitched that one revolu-
tion of the thumb-nut moves the cells two degrees. The outer
nut, or the one for the left cell, is so arranged that by slipping
it forward both cells may be revolved at once.

7. The phorometer, by being supported at both ends, must
be level when the rest of the instrument is, as it has no chance
to sag.

Dr. Stevens, in a recent article, puts special emphasis on
the fact that to get accurate results with his instrument it must
be level and at three or four inches from the patient's eyes, as
at that distance there is little if any error made by the ocular
muscles to overcome the prismatic action. This principle has
been carefully carried out in the construction of this instrument,
making it, according to Dr. Stevens' definition, the most accu-
rate of its class. The head, too, being comfortably supported,
the patient is not nearly so apt to get out of position.

The advantages alleged for this instrument over all others
are: 1. Rigidity. 2. Better position of the lens-holders. 3.
Comfort and stability of the patient secured by forehead- and
chin-rests. 4. Ease of control of the chin-rest. 5. Improvement
in the revolving cells. 6. Greater accuracy in the phorometer.

Apologizing for the length of this article, and hoping others
may find the bracket in some measure as convenient and accu-
rate as I myself have, I will close by saying the instrument is
made for me by Queen & Co., of Philadelphia, which is a guar-
antee that the workmanship is all that could be desired.

No. 113 Stebbins Street.
W. Galt, whose *Treatment of Insanity* is an encyclopedia of psychiatry hardly equaled as a compendium of current literature at the present time. American alienists, he says, have been fully aware to current movements of psychiatry. Dr. Galt stated that in the treatment of insanity the efficacy of mesmerism appeared doubtful, and he cited Esquirol to the effect that magnetism had been tried, especially in Germany, but facts in regard to its use in France were not exact or well observed. In 1813 and in 1816 he (Esquirol) made a trial, with M. Farin, upon eleven insane women. Only one (remarkably hysterical) had yielded to the magnetic influence, but her mental state had undergone no change. It had produced no effects on the ten others. These trials had been made in the presence of M. Desportes, administrator of hospitals, and other persons, among them many physicians. These same trials Esquirol had repeated many times with various magnetizers, without more success. Dr. Galt also cited Guislain as follows: "As to animal magnetism, the results obtained from it are unsatisfactory; it is a means with which we ought to be on our guard. More than once it has produced disorder of mind."

Experiments were made in Richmond, Va., in 1842, of which Dr. Galt gives the following account: There was perfect silence enjoined the whole time. The patient seated himself on a chair, and the magnetizer on a higher seat in front of the patient, and at least a foot away from him. He collected himself for a few minutes, during which he held the patient's thumbs, and remained in this position until he felt that the same degree of heat was established between the patient's thumbs and his own. Then he drew off his hands, turning them outward, and placed them on the patient's shoulders for nearly a minute. Afterward he carried them slowly, by a sort of light friction, along the arm down to the extremities of the fingers. This was repeated five or six times. Then he passed his hands over the head, kept them there a few minutes, and brought them down, passing before the face at a distance of one or two inches, to the epigastrium, where he stopped again, either bearing upon the region or without touching it with his fingers. And thus he came slowly down the body to the feet. Passes or motions were repeated during the greater part of the course, and when the magnetizer wished to finish it, he carried his hands even beyond the extremities of the hands and feet, shaking his fingers each time. Finally, he performed some transient motions before the face and the chest at a distance of three or four inches, by presenting his hands, which were near each other, and removing them abruptly. Then, standing before the patient, he clasped her hands firmly in his own and fixed his gaze intently on her, her eyes being steadily directed to him during the whole process. About four minutes afterward he began to pass his hands alternately, or both at a time, from her forehead to her fingers, and continued this for two minutes; he then passed his right hand against her forehead, repeating the passes with his hands for nine minutes; he again placed his right hand on her forehead, making passes for about eight minutes, the time varying, of course, with the individual.

According to Caldwell, says the author, there are three schools of magnetism: 1. That of Chevalier Barbarini, who believed the effects to be owing merely to faith and volition. 2. That of Mesmer, who referred them to the passes only. 3. That of the Marquis de Puységur, who attributed them to both. All three schools, more or less modified, are represented to-day among students of hypnotism.

Elliotson, who alleged that he cured periodical insanity by mesmerism, produced the sleep merely by suggestion. His will was powerless in all mesmeric experiments. He never accomplished anything by it alone. He had willed excitement of distinct cerebral organs, and willed powerfully, but always in vain. He had three patients, with each of whom he had formerly taken some weeks to induce sleep, who now went to sleep when he merely raised his hand or looked at them, when they were prepared to expect sleep. He told them that if they sat still he would mesmerize them with the door closed upon them. He shut the door, walked into another room, turned back, and found them asleep. While doing this, he thought as little as possible of them, and busied himself with other things.

According to Dr. J. K. Mitchell, says Dr. Kierman, mesmeric effect is usually producible within ten minutes, and at the first sitting, although some persons have yielded only after long and repeated trials. In general, unless marked effects are produced in half an hour, subsequent trials are useless. Sleep is dissolved by time alone, the natural duration being from thirty minutes to five hours. Artificial awakening sometimes results from merely a single wave of the hand. The nervo-sanguineous temperament is the most susceptible to the action of mesmerism. The young and the old have the least susceptibility, and between twelve and twenty is the most favorable age. The influence of sex is very small. Mesmerism should be employed temporarily to relieve affections of a nervous character, when the usual means fail, and even here with due precautions. It has sometimes, especially in unpracticed hands, produced frightful disorders, both of mind and of body.

Ennemoser said that the hands were the proper organs of the will, through which volition became action. The greater the quietness of the manipulation, the less there was of bustle, gesticulation, and ceremony, the more advantageous it would be to the patient, whose imagination should not be struck with the oddity of the proceeding. No uneasy curiosity should be excited; the effects should steady on him unawares. The susceptibility to mesmeric impressions is in inverse proportion to the general organic force, and, more particularly, of the patient's nervous power.

Passavant stated that the eye and the hand not only received, but gave; the other senses only received; the sense of feeling became, in the hand, the sense of touch; from the continual activity of this sense a greater consumption of nervous power went on in the hand, particularly at the extremities of the fingers, and in consequence, probably, an increased efflux of the nervous aether; this process might be heightened in intensity by the action of the will. In the manipulations, the hand was to rest on the part affected (where the disease was local), or on those places where the most important nervous structures were situated, in particular, the head, the center of the cerebral, and the stomach, the center of the ganglionic nervous system. Passes made with the point of the fingers, or the palm of the hand, whether with or without contact, must be carried from above downward, from the brain toward the extremities. From these and many other instances, says Dr. Kierman, it is evident that the American alienists of the first half of the present century were familiar with, had experimented with, and had clearly anticipated almost every position of modern investigators concerning hypnotism. They recognized its dangers, its psychological basis, and the fact that an element of morbidness was needed to predispose the patient to susceptibility to hypnotism, also that the insane were subject to suggestion only in a limited degree.

The Late Dr. James Hewitt.—At the regular meeting of the New York Otolological Society, held at the Academy of Medicine on January 22, 1895, the following was unanimously adopted and incorporated in the minutes of the society:

The New York Otolological Society desires to place upon its minutes the sense of the loss it has sustained in the death of Dr. James Hewitt, one of its founders.
Although but a young man at the time of his death, Dr. Hewitt had already attained a prominent position in his profession, and had he lived would undoubtedly have become one of the distinguished authors of his time.

With a singularly retiring and quiet nature, he had a most genial and cheerful disposition, and a simplicity of bearing and kindness in speech and manners that endeared him alike to his friends and to his patients.

Resolved, That these resolutions be printed in the medical journals of this city, and that a copy of the same be sent to the family of the deceased.

[Signed.] Gorham Bacon, M. D., Committee.

Starvation Insanity.—The Nouvelle iconographie de la Soufflitré for December contains an interesting article in which M. E. Brissaud gives an account of a case which had come under his observation. The patient, a girl, nineteen years old, had fallen on her right hip about ten years before the author saw her. This was followed by a painful swelling, which rapidly disappeared, but left in its place a painful condition of a psychical nature, which persisted for many years. At certain times it was uppermost in her mind and, by an association of ideas, brought on various troubles, such as swelling of the abdomen and vomiting, or else angina and syncope, etc. In the beginning, a very excusable error in diagnosis was made in calling the disorder coxalgia and in prescribing treatment appropriate to that disease. Subsequently, when serious symptoms supervened in consequence of this error, it was thought to be an ossiflent abscess with peritonitis, and, if the patient’s general condition at that time had permitted, laparotomy would have been performed.

The appearance of these disorders following hyperesthesia of the hip is, says the author, on the whole, easy to understand. It was but a fresh example of hysteria simulating coxalgia, peritonitis, etc. With regard to the mechanism which governed the association of all these ideas, it is probable that the physician’s diagnosis, his questions, his examination, his treatment, etc., were not without their influence on the patient. It is also easy to understand how the idea of starving herself became a fixed one in her mind. When she was about sixteen years old she was an object of ridicule among her companions because of her size, and, in her nervous condition, the desire to reduce her flesh became a mania, and, in order to realize this desire, the sorest and the simplest way was not to eat, or to vomit whatever she had eaten, and she began systematically to refuse food and to vomit. She lost flesh rapidly and two or three times was at the point of death. At one time, in an access of religious frenzy, she was suddenly cured by taking two teaspoonfuls of Lourdes water. Another time, imagining that the Virgin had abandoned her, she concluded that she was a great sinner, and accordingly she made a number of confessions and stated that she had committed many sins, and, as the Virgin had not found her worthy of pardon, she would die in her sins. All this, says M. Brissaud, is the logical result of this form of delirium.

In this condition she was brought to the hospital on April 17, 1894. Her face was vacant and emaciated, and it had an old look. The bones of the face, the shoulder-blades, the ribs, the vertebral apophyses, the bones of the pelvis, and those of the limbs were very sharply defined. The skin was brown, wrinkled, flabby, and dry, and hung in folds over the parts it covered. The hair was dry, and thin in spots, particularly behind the ears, where two patches of alopecia were to be seen. The nails were irregular, and the patient gnawed them incessantly. The fatty tissue had almost entirely disappeared and the mus-
idea, we see the hysterical person starve with an extraordinary facility and soon arrive at the stage where marasmus and consumption set in. It is only exceptionally that the physical decline exceeds these limits, but when it does, no matter how vivid the fixed idea of recovery may become, death is inevitable.

The United States Pharmacopeia.—In an exhaustive and very interesting article by Dr. Charles Rice, introductory to a series entitled The Study of Pharmacy, published in a recent number of the Pharmacetical Era, we find the following:

"A pharmacopeia should represent the broad results of therapeutic observations and investigations accepted by, or at least acceptable to, the medical profession at large in the country for which the work is written. In general, therefore, it should not introduce insufficiently tried new remedies or methods, but should accept only those which have, by matured and careful study, been found worthy of recognition. An exception to this rule may occasionally be found admissible, when a new form of preparation is introduced to take the place of one which has been found unsatisfactory. On the other hand, it ought to contain all remedies which are used in legitimate practice, and which the physician openly and designately uses to obtain definite results. At the present time it is impossible to open any medical periodical or text-book on therapeutics without constantly encountering the names of the newer synthetic chemical remedies, such as antipyrine, sulphanil, phenacetine, aristol, etc., and yet these are kept out of the United States Pharmacopeia. Up to the year 1890 there was probably a sufficient excuse for this, because the permanency of many of these compounds was not yet fully assured, and the proprietary claims surrounding most of these substances were regarded as an ethical barrier against their recognition. It appears, however, that the views regarding the status of these remedies are gradually changing in favor of their future recognition. Most surely they should not be classed with proprietary nostrums, for in most cases their chemistry, mode of manufacture, constants of nature, reactions and tests are scientifically determined and known, and it is equally certain that they will be employed by the medical profession, whether they are recognized by the pharmacopeia or not. Their multiplication, aside from other causes, will gradually diminish the number of many of the more old-fashioned and, to a large extent, empirical preparations now official. Eventually the time might arrive when the majority of the energetic and efficient remedies used by the physician would have to be looked for in works of reference outside of the pharmacopeia. It is to be hoped that this matter will be well considered and that the present restrictions will be removed at the next convention.

The question has often been raised, Why did the Committee of Revision not introduce a table of doses in the pharmacopeia? And it has been answered at various times, more or less completely, sometimes at great length. This may be done more briefly as follows: Doses of medicines can and should be determined on and authorized only by medical men, who are competent to judge of their effects. This work can not be undertaken by pharmacists. As long as the medical colleges, societies, and associations do not authorize their delegates to the convention, and their representatives, if they have any, in the Committee of Revision, to vote for the insertion of doses, none of them would feel justified in consenting to it, as there is a deep-seated impression abroad that the establishment of an official table of doses would place a dangerous weapon into the hands of unscrupulous persons, and might involve many physicians in suits for damages. All efforts, therefore, in favor of the introduction of doses into the pharmacopeia should be directed to the medical profession, and no blame for their omission should be attached to the Committee of Revision, which is powerless in the matter. It is suggested that a proposition be made to the medical profession, probably best to its representative body, the American Medical Association, to sanction a table of doses, prepared by a committee of therapeutic experts, to be printed in the pharmacopeia, with the distinct announcement that the doses given are the average ones to produce the ordinary expected effects, but that every physician has the right to use larger or smaller doses whenever such may, in his judgment, be required."
Antispasmine.—In the Revue internationale de médecine et de chirurgie pratiques for January 10th there is an abstract of an article which was published in the Journal de médecine de Paris for December, 1894, in which the writer says that under this name a so-called combination of sodium salicylate and soda narseine was put on the market in the year 1893. This product was first experimented with by Professor Demme, of Bern, who recommended it as an antispasmodic hypotonic. Experiments made since then by various writers seem to show that this medicament is very uncertain and has no therapeutic value sufficient to justify its use, at least among adults. The following formulas are employed by Professor Demme: 1. Antispasmine, 15 grains; cherry-hazed water, 150 grains. Fifteen drops of this solution are given to children with whooping-cough twice a day. 2. Antispasmine, 8 grains; distilled water, cough, and mulberry syrup, each, 150 grains. For an adult the dose of this solution is a dessert-spoonful three times a day. Antispasmine is a white powder, very soluble in water. The dose for children is from 1/2 to 1/2 grains, and for an adult from 3/4 to 4/4 grains.

A Race of Heavily-furred Cats.—An example of the adaptation of animals to circumstances is given in the Lyon médical for December 9th. In America, says the writer, there are large underground warehouses for the preservation of meats, poultry, and fish, where the temperature is maintained at about three degrees below the freezing-point. It was thought that this intense cold would cause the disappearance of rats and parasites, and in fact, in the beginning, they died. Gradually, however, they became accustomed to the intense cold, and were soon covered with a very thick fur extending from the nose to the tip of the tail.

An experiment was then made with cats, but they all succumbed to the cold, until a cat with unusually thick fur was brought in. This cat lived, her fur became still longer and heavier, and one day she gave birth to seven kittens, which were the objects of great care. At the present time these cats are entirely acclimated and have numerous descendants.

This fact, says the writer, calls to mind the savage cats in Canada, which have short tails, enormous eyebrows and whiskers, and a very thick fur. These cats, when brought out on a hot day, die, sometimes in a few hours, under the influence of the light and heat.

Multiple Sarcoma of the Skin in a Newborn Child.—At a recent meeting of the Gesellschaft für innere Medizin, of Berlin, a report of which appeared in the Mercure médecin for January 24, M. Karweski presented the case of an infant, seventeen months old, born with small tumors irregularly distributed over the entire surface of the body and not having any connection with the nerves or with the blood-vessels. As the child grew larger the tumors increased in size. At the time of the meeting some of them had attained the size of a fist. They were flabby, movable, and covered by skin which was the seat of vascular dilations. One of these tumors had been cut out and the microscopical examination had shown that it was a question of angiosarcoma. The sarcoma might have had as a starting point the outer coat of the blood-vessels, an occurrence which, the speaker remarked, had been generally contested.

Cerebral Sclerosis due to Influenza.—The Progrès médical for January 5th contains a report of a recent meeting of the Société médicale des hôpitaux at which M. Rendu related the histories of two cases of cerebral sclerosis following an attack of influenza. The first case was that of a young and vigorous man, who had presented successively, during recovery from the disease, an incomplete, transitory hemiplegia which had lasted for fifteen days. Four months later symptoms of neurasthenia set in, followed by astasia, and finally symptoms of sclerosis in disseminated patches. The second case was that of a child, three years old, who had had an attack of anergyitis which had been contracted during an epidemic of grippe. The child had been seized with convulsions, Jacksonian epilepsy, then transitory hemiplegia followed by partial hypertrophy of the limbs. M. Rendu thought these cases were of much interest clinically, for, although the question of local or diffuse sclerosis had been much better known from an anatomical point of view since the appearance of M. Marie’s essay, the same could not be said from the clinical point of view.

The Treatment of Miliary Tuberculosis with Guaiacol.—The Journal des praticiens for January 12th publishes an article on this subject in which the writer says that since the year 1893 simple painting with guaiacol has been employed in cases of febrile tuberculosis. Bard, Lepine, and others have demonstrated by a series of observations that its antipyretic action does not improve the condition of consumptives with cavities, that it may perhaps ameliorate sclerosis, but that it produces better results in limited miliary tuberculosis of a doubtful diagnosis. These last curative results differ from the transitory antipyretic action obtained in ordinary tuberculosis. The writer relates the histories of four cases in which this treatment was employed, and the following conclusions from a physiological point of view, he says, may be drawn: 1. The antipyretic effects of guaiacol are rapid and lasting in miliary tuberculosis. 2. The effects on nutrition are shown by the amelioration of the general condition and of the local lesions. 3. Sometimes cutaneous erythema, hypoesthesia, and a tendency to collapse may be observed, which are due to the impurities in the guaiacol, and not to the medicament itself. Its positive indication is true tuberculous fever with the formation of new granulations; its contraindication is hectic fever.

The method of administration consists in varying the dose from eight to thirty grains at each application. Bocq prescribes the following mixture in order to produce the greatest tolerance: Equal parts of chemically pure guaiacol and sweet-almond oil. The backs of the hands are painted with this mixture and immediately covered with cotton, which is kept in place with a bandage.

A Russian physician, Bartoszewicz, who experimented with this treatment on sixty-five patients in Dr. Laminowsky’s service at Kharkow, employed compresses of guaiacol on the anterior part of the chest and over the back. A piece of linen was moistened with from twenty-five to thirty drops of pure guaiacol and applied on the skin, which was then covered with waxed paper kept in place with a bandage, and allowed to remain for from one to two hours.

The Dangers of Beta-naphthol.—The British Journal of Dermatology says that Dr. Ilanz (Semaire médicale, No. 59, 1894) points out a possible danger attending the use of betanaphthol as an ointment. Two children, aged eight and six years, were treated for scabies with a salve containing two per cent of this drug. Three weeks later, when the skin affection was cured, albuminuria and edema of both legs appeared, and one child died. Neither of the children had suffered from symptoms of renal disease before. A post-mortem examination was obtained, and the diagnosis confirmed.
THE MILK SUPPLY OF NEW YORK
AND THE TESTS OF ITS AVAILABILITY FOR INFANT FEEDING,
WITH A REVIEW OF THE METHODS OF STERILIZATION.*

By EMILY LEWI, M.D.,
FROM THE LABORATORY AND SERVICE OF DR. HENRY KOPLIK,
GOOD SAMARITAN DISPENSARY, NEW YORK.

There seems to have been for some time a gradually growing opinion among the profession that the milk supplied New York city is primarily of an inferior quality and therefore unfit for infant feeding. It was with the view of ascertaining, if possible, the real facts concerning so important a question that a systematic examination of the milk supply of the city was undertaken by the author. If the milk which reaches the average store or dairy, especially during the heated term, be of questionably quality, certainly the further preservation of such milk is unavailing. The investigations extended over a period of some months—March to October—of the year 1894; a great number of tests were made; only enough for general deductions can be noted in this paper. In order that the results might be as far-reaching as possible, milk from many localities was procured. Since the largest summer mortality among infants is to be found in the tenement house districts, it will be observed that samples of milk were investigated from the most densely populated tenement districts; there were specimens from a less populous district, also from uptown on the east side, and likewise milk from exquisitely kept dairies on Third Avenue and the west side. Only by varied comparative tests could a broad result be obtained. We know of no better milk than fresh cow’s milk procured at the time of milking at a first-class country dairy. Such a milk was taken as standard and with this the city milks were compared.

Milk taken from various sources in New York and at various periods of the year has much the same physical characteristics. It has the same volume of cream (twelve to fourteen per cent.), and it contains much the same amount of fat. The milk, after cream has been carefully separated, has an average specific gravity. The milk, in other words, is an average mixed milk. These facts have been investigated by Dr. Koplik.

There are here and there signs of adulteration, but the physical characteristics of milk furnished by contractors as delivered to them here in the city are uniform. The above, therefore, being fixed, the freshness and quality of milk as dealt out at the various stores is of interest as far as baby feeding is concerned.

In looking around for a reliable test we must choose that which promises and has given the best average results. No one known test can be said to meet so many requirements as the chemical test. The test chosen was Soxhlet’s method as perfected by Plauth, which is based on the following principle: All fresh milk shows amphoteric reaction to litmus paper, owing to the presence in milk of both acid and alkaline phosphates. To phenolphthalein, however, milk acts as an acid; if a two-per-cent. alcoholic solution of phenolphthalein is added to a quantity of milk, and baryta solution be slowly titrated into the milk, a pink discoloration of the milk takes place, which rapidly disappears; when that point is reached at which the acid phosphates have become neutralized, one drop more of an alkaline solution gives a permanent pink hue to the milk. The amount of the solution needed to effect this is read off on the burette and is a measure of the acidity of the milk. Plauth used a normal solution of baryta of which one cubic centimetre was equal to 5 MgSO₄.

Each test was made as follows: Into each of two beakers twenty-five cubic centimetres of milk was poured, and to each of these was added two cubic centimetres of a two-per-cent. alcoholic solution of phenolphthalein. As the barium hydrate was slowly dropped into one of them, the milk was stirred with a glass rod; at intervals the milk in the two vessels was compared; the slightest tinge of pink left in the milk shows the titration to be complete. The amount of barium solution required is read off. Each cubic centimetre of the barium is equivalent to 5 MgSO₄; if four cubic centimetres of the barium were employed to neutralize twenty-five cubic centimetres of milk, then a hundred cubic centimetres would require four times as much, or sixteen, whose SO₄ equivalent would be 80 Mg. In the tables the acidity of a hundred cubic centimetres of milk will invariably be given.

A chemical rather than a bacteriological test was made, owing to the greater simplicity and practicability of the former as an everyday test. Clauss, in his researches, found that the increase of bacteria was forty-eight millions before there was an appreciable advance in the acidity. Plauth considers these results erroneous and due to the tremendous dilution of the milk by Clauss. Plauth bases his most valid objection to the bacteriological method upon the fact that plate cultures require a minimum exposure of forty-eight hours before reliable data can be obtained. A delay of forty-eight hours after the arrival of the milk in the city would render it unfit for use.

Plauth, in his tables, shows that there is always a difference in acidity between fresh milk boiled and unboiled; that the difference diminishes as the milk grows older. The lesser acidity of the boiled milk is due to the acid CO₂ which is driven from the milk on boiling. If two samples of milk are considered, a boiled and an unboiled specimen, should there be little or no difference between them, the milk is an old milk.

* Read before the Section in Pediatrics of the New York Academy of Medicine, January 10, 1895.
The average morning acidities of both the city and country specimens were found to vary between 80 and 90. A safe morning limit, provided a carefully prepared baryta solution were employed, would be between 75 and 95. However, it is desirable to lay stress upon the fact that a milk whose morning acidity is 80 is not necessarily a better milk than one whose acidity is 90. They are both within safe limits.

But the rate of increase in the acidity of milk is the criterion by which it must be judged. Soxhlet showed that fresh milk for some time after milking does not increase in acidity. This interim of stationary acidity is known as the incubation period of the milk.

Plath's Bacterial Table—Milk in Thermostat at 25° C.

</tbody>
</table>

Showing an appreciable increase in acidity at the end of the fifth hour, the bacterial count at that time somewhat over half a million; when the incubation period was well over, the bacteria numbered eight millions.

During the last third of the incubation period Soxhlet allows that there may be a slight appreciable increment in acidity, and, as will be seen in the table, Plath showed that the bacterial state is stationary until the last third of the incubation period; but when this period is over there is a decided increase in acidity, more and more rapid as the milk approaches the coagulation point. He also shows that there is a stage at which milk coagulates on boiling before spontaneous coagulation occurs. Both Soxhlet and Plath demonstrated that the length of the incubation period depended upon the temperature at which the milk was kept, and the cleanliness attending its procured and preservation.

\[
\begin{array}{cc}
\text{Milk kept at 15° C.} & \text{Milk kept at 20° C.} \\
\text{Acidity} & \text{Acidity} \\
\text{Milking time} & 84 & \text{Milking time} & 84 \\
\text{Four hours later} & 84 & \text{Two hours later} & 82 \\
\text{Eight hours later} & 83 & \text{Eight hours later} & 84 \\
\text{Twenty hours later (end of incubation period)} & 84 \text{Ten hours later (end of incubation period)} & 90 \\
\text{Twenty-five hours later} & 98 \text{Twenty hours later} & 112 \\
\end{array}
\]

From this we observe the shortening of the incubation period by ten hours in the milk kept at 20° C.

As regards the second factor, cleanliness, its influence on the acidity was demonstrated by Plath, and will be shown later on in our own tables.

The period of incubation of milk is the only period during which milk is an available infant food; moreover, the limits of this availability have by common consent been fixed in the first two thirds of this period. It will therefore be self evident that the shortest incubation period for milk not kept on ice will be during the summer months, the longest in the winter time.

A series of tests of fresh country milk were made. Milk was obtained each morning at a country dairy in Essex County at milking time, the milk being still warm. The milk was taken from a thirty-five-quart can, and was therefore the mixed milk of six or seven cows. The dairy was clean, the dairymen took no special precautions about washing their hands, the cows' teats were washed off with a little of the milk of the first milking. The milk pails were scrupulously clean. The milking was over at about 6 a.m. The milk was taken directly to the country laboratory and emptied into sterilized nursing bottles for further use. A warm summer day; mean temperature of the day, 22-6° C.; showed amphoteric reaction:

<table>
<thead>
<tr>

<td>92</td>
<td>86</td>
</tr>
</tbody>
</table>

\[\text{August 24th.} \text{— A warm day; amphoteric reaction; 29° C. mean temperature:}\]

\[
\begin{array}{cc}
\text{Dairy, raw.} & \text{Dairy, boiled.} \\
\text{Milking time} & 84 \text{ 72} \\
\text{Three hours later} & 84 \text{ 84} \\
\text{Eight hours later} & 84 \text{ 86} \\
\text{Nine hours later} & 100 \text{ 82} \\
\end{array}
\]

\[\text{August 26th.} \text{— Amphoteric reaction; mean temperature, 24° C.:}\]

\[
\begin{array}{cc}
\text{Dairy, raw.} & \text{Dairy, boiled.} \\
\text{Milking time} & 84 \text{ 72} \\
\text{Six hours later} & 84 \text{ 84} \\
\text{Eight hours later} & 84 \text{ 86} \\
\text{Nine hours later} & 86 \text{ 86} \\
\end{array}
\]

\[\text{August 27th.} \text{— Amphoteric reaction; 24° C.}\]

\[
\begin{array}{cc}
\text{Dairy, raw.} & \text{Dairy, boiled.} \\
\text{Milking time} & 86 \text{ 76} \\
\text{Six hours later} & 84 \text{ 86} \\
\text{Nine hours later} & 86 \text{ 92} \\
\text{Twelve hours later} & 92 \\
\end{array}
\]

The difference between the raw and boiled milk is very evident in every case.

The lengthened incubation period on a cool summer day was clearly brought out; mean temperature, 15° C.:  

\[
\begin{array}{cc}
\text{Milk temperature} & \text{Dairy, boiled.} \\
\text{Milking time} & 84 \\
\text{Four hours later} & 84 \\
\text{Seven hours later} & 82 \\
\text{Ten hours later} & 84 \\
\text{Three hundred hours later} & 86 \\
\text{Seventeen hours later} & 92, \text{end of incubation stage} \\
\text{Twenty-four hours later} & 104 \\
\text{Thirty hours later} & 130, \text{curdles on boiling.} \\
\text{Thirty-eight hours later} & \text{curdled.} \\
\end{array}
\]

The incubation period lasts about seventeen hours, then more rapid rise of acidity.

The effect of extra precautions as regards cleanliness at milking time gave interesting data. Specimens of middle milk were milked into sterilized tubes and plugged with sterilized cotton (Series A). A second series was taken,
after washing the udder and teats thoroughly with warm boiled water; the hands also were well washed with hot boiled water (Series B).

Reaction amphoteric, mean temperature on that day:

The extra care lengthened the incubation period a number of hours. With similar experiments Plauth had most brilliant results, the milk remaining sterile twenty-eight hours.

The city tests were begun in February and were as follows:

In winter weather city milk remains within the incubation period twenty-four hours, coagulation taking place in seventy-two hours.

Of greatest comparative interest, however, are the tests made during the summer months in New York, as compared with the country experiments. The city milk was on every occasion amphoteric in reaction when first obtained in the early morning. The milk delivered at the dispensary laboratory in the morning will be designated "laboratory" milk; this milk is known to be from a reliable dairy.

Incubation period lengthened on a cool day to nine hours without the aid of ice.

It will be seen that the incubation stage of fresh country milk on a hot summer day as compared with city milk exceeds it by about two hours; that city milk gives amphoteric reaction at the time of the morning tests; that there is a difference between the morning raw and boiled specimens in the city as well as in the country, but that this difference is uniformly greater in the case of fresh country milk. In not one instance was city milk upon its arrival in the morning beyond the incubation stage.

Furthermore, that the preceding deductions might be beyond dispute, milk from tenement-house districts was subjected to a most severe test—the thermostat test of Plauth, considered crucial by him.

As a result of innumerable examinations of milk whose source was known to him, Plauth came to the following conclusions:

(a) Fresh, clean milk—i.e., in which at milking time cleanly precautions are taken—remains unchanged in its acidity after five hours, at least, of thermostat temperature.

(b) Fresh milk which is not clean remains unchanged four hours, but in the fifth hour shows an initial increase in acidity.

(c) Moderately clean milk, in the first two thirds of the incubation period, shows a beginning rise in acidity after three hours and a half; after two hours may show slight decrease in acidity.

(d) Milk in the last third of the incubation stage shows in two hours either no rise or a very slight rise; in three hours a marked increase in acidity.

(e) Milk beyond the incubation stage shows appreciable increase in acidity in one hour.

City milk from the poorer districts gave the following values. The thermostat was kept at a temperature of 36°5 C. to 36°75 C. Examinations extended over a period from September 26 to October 7, 1894:

These tables corroborate previous experimentation, and show absolutely that milk on its arrival in the city is still within the incubation stage and remains thus within varying safe periods of time, and is a safe infant food. In only one instance did we find the milk so far advanced as the last third of the incubation stage (Test I).

The acidosities which have been noted give evidence that so far as the age and acidity of milk upon its arrival in the city is concerned, milk from the better neighborhoods can lay no claim to superior excellence. On a very close September day milk was obtained at 7 A.M. from filthy stores on Ludlow, Bayard, and Ridge Streets, and from an excellent Third Avenue dairy.

At 1:30 P.M. milk was again procured at the downtown stores and dairy; a portion of the morning's (7 A.M.) milks had been put into an ordinary refrigerator well stocked with ice, and corresponding as nearly as possible to the temperature at which the store specimens should be kept.

The milk procured in the morning and kept on the ice in clean bottles showed about the same result in the case of the dairy milk. But the milk procured in the early part of the afternoon in the small shops showed the incubation period about over at the time that the second sample was obtained.

Carelessness as regards cleanliness or the temperature at which the milk was kept, or possibly both fac
tors, showed the disadvantage which would accrue in further preservation of the down-town milk procured at 1.30 p.m. For such a state of affairs the storekeeper alone is responsible, and he, not those who supply him with milk, deserves criticism.

New York city milk is therefore, both in the winter and the summer, still within the incubation period on its arrival in the city, the incubation stage lasting twenty-four hours in the winter, thirteen to seventeen hours on a fairly cool day, and five hours on a hot summer day, after the milk reaches the city.

The excellent condition of the milk when it reaches the New York market is a tribute to the American method of shipment. Many hundreds of car loads come from a distance of two hundred to three hundred miles on slow milk trains. These refrigerator cars are well stocked, and the cans are filled full, the milk, as a rule, reaching the city perfectly sweet. This milk, if prepared early, we consider a good infant food.

Having established the status of milk upon its arrival in the city, the natural question arises, What further steps shall be taken to render this milk fit for infant use? In the average tenement-house family in the summer time milk is not procured once a day, and then in sufficient quantity for the entire day, but it is bought in two or three installments. Again, granted that sufficient milk for the twenty-four hours be bought, this may or may not be put on ice. No more than one out of five families in our crowded tenement-house district can afford the luxury of ice (as estimated by a careful observer), and these at best spasmodically. Therefore, as has been shown, in the summer time the milk must be bought early in the morning, by eight o’clock, and the quantity for twenty-four hours should be prepared for the baby by 10 a.m. Milk procured later in the day is unreliable in the poorer districts.

Milk was subjected to various procedures to ascertain their effect on restraining the acidity. Sterilized nursing bottles were invariably used, each bottle sufficient for but one test. The milk was kept at ordinary room temperature, as in the preceding tabulation.

The process of filtration, to which attention has been somewhat directed of late, was employed. Here again both city and country milk was taken. The Seibert aluminum filter, as of most recent date, was used.

The preceding series of experiments indicate the negative influence of filtration as delaying the souring of milk. Filtration, therefore, may justly be said to have no effect on the activity of the *Bacterium lactis*.

Investigations were made concerning pasteurization as a preservative measure. Tests were made daily, extending over a period of twenty days. Laboratory milk, milk from small city stores, and fresh country milk was taken. The Freeman pasteurizer was employed, the bottles placed in the boiling water, remained there thirty minutes, were quickly cooled, and left standing at room temperature.

So much confusion as to the correct understanding of the process of pasteurization has crept into the recent medical literature that it may not be amiss here to give an exact exposition of the term and the manner of its origin. Pasteur, in both his works, *Etudes sur le vin* and *Etudes sur la bière*, shows in a conclusive and classical manner that wine and beer freshly made contain, in addition to the alcoholic ferment, *Mycoderma viini* and *levure de bière*, which are normal to the beer and wine, and certain extraneous microorganisms which have contaminated the wine and beer during the process of manufacture. These extraneous organisms (the so-called *Mycoderma aceti*, etc.) cause the beer or wine to spoil subsequent to the storage. Pasteur’s great merit was to have logically devised a method of destroying these foreign bacteria and yet leave intact the alcoholic ferment (levure) which are the essential agents in the formation of good wine. For to destroy both the alcoholic ferment and the foreign bacteria would leave the wine but an indifferent fruit juice, whereas to leave both in the wine results in the so-called deterioration (souring or bitter taste) of the wine (*maladie du vin*).

Pasteur found that, by subjecting the freshly made wine to a temperature varying from 50° to 60° Celsius, the alcoholic ferment retained its life, while all foreign bacteria (*Mycoderma aceti*, etc.) were killed. Wine thus treated never turned sour or bitter, but as time passed became, according to the quality of wine and the variety of alcoholic ferment, of greater vigor and bouquet. This is the only process worthy of the term pasteurization. As to milk, pasteurization has been con-
aced by Pasteur himself to be useless so far as the preservation of the milk is concerned, for the low temperature of 50° to 60° C., while it will kill the Mycoderma ooceti of the wine or beer, will not disturb the vitality of the Bacterium lactis, which is the chief agent in causing milk to spoil. Authors who have, therefore, used the term pasteurization as applied to temperatures of 70°, 75°, or 80° C. have rather, to say the least, misapplied and strained a very important term of bacteriological nomenclature.

</tbody>
</table>

On a warm summer day, pasteurized milk has a fairly stationary acidity ten to twelve hours after pasteurization; the acidity then rises slowly, and twenty hours after pasteurization the milk is curdled. In cooler weather the incubation period is lengthened to twenty-four hours or more. The growth of the Bacterium lactis is retarded for about six hours as compared with unpasteurized milk. The coagulation of pasteurized milk, twenty hours after pasteurization, and an increase in half that time, marks pasteurized milk a dangerous infant food. Bitter, in his article in the Arch. für Hygiene, 1890, gives tables in which at an exposure of 22° C. the pasteurized milk coagulated in eighteen hours, thus confirming the tables of this paper. Bitter advocated a pasteurization of the milk at the country dairy, the milk thence to be sent in freight cars to the large cities. His method may meet the requirements of Germany, but not those of this country, where distances are longer, and slow freight trains from distant points require eighteen to twenty hours. Pasteurized milk would by that time be curdled (as shown above) in the warm weather, the Bacterium lactis for some hours having again had full sway.

Flügge states uncompromisingly that milk pasteurized at the country dairy must, upon reaching the city, be treated as unpasteurized milk, so far as its adaptation for an infant food is concerned.

City and country milk was sterilized and the results noted. The temperatures at which the sterilization was effected were absolutely under control. In each compartment of the laboratory steam sterilizers are placed fifty bottles; not every bottle can have exactly the same temperature, however carefully the steam may be regulated. Into the middle bottle of the top compartment of each of the three laboratory sterilizers a thermometer was introduced and a temperature 90° to 92° C. maintained for forty minutes.

These bottles were tested daily.

Below the 90° C. limit the milk could not be considered absolutely stationary in acidity longer than twenty-four hours. In several instances where the milk was sterilized at 87° C. to 90° C. the milk began to increase slightly in acidity twenty-four hours after sterilization; the weather had been unusually trying—32° to 34° Celsius at 3 P.M.

Sterilization above 92° demonstrated a greater lapse of time before any change occurred.

Of three bottles sterilized at 99° C., August 14th:

<table>
<thead>
<tr>

<td>still unchanged</td>
</tr>
</tbody>
</table>

For everyday practical purposes, sterilization at low temperature, 90° to 92° C., meets all requirements. Although this temperature renders the milk far from absolutely sterile, the Bacterium lactis is rendered inert for two days at least at a summer temperature.

Flügge contends that the acidity of partially sterilized milk is no measure of the condition of the milk, as this milk undergoes alkaline fermentation which is due to the potato bacillus and its spores, which are not killed at so low a temperature. The activity of this bacillus causes a peptonization of the milk, evidenced by a clear zone which may be seen below the zone of cream. Milk sterilized forty minutes at 90° C. to 92° C. gives no evidence of this peptonization for a minimum interval of five days. Even this sterilization temperature is not safe if milk is to be taken on a long journey for weeks, nor is it a method by which milk can be conserved for any indefinite period.

But it is safe when milk is prepared daily for infant diet.

The facts enumerated show plainly that by this chemical examination the milk which is delivered at the New York retail stores is, if sterilized early in the morning, a wholesome food for babies. The chemical test is, however, elaborate and somewhat complicated for popular use, but is certainly most efficacious and desirable for labora-
torics or large milk depots. Allowing slightly for a personal equation in titration work, we think this method could be satisfactorily introduced. The baryta solution is at once covered with crude petroleum, and, if carefully prepared, remains constant for a number of months.

A milk which at the time of its arrival in the city has an acidity of 95 or over, and in which the difference between the boiled and the raw specimen is slight or perhaps not appreciable, should be withheld, and an hourly test should be made; any increase of acidity within an hour or two hours should condemn the milk as poor milk, and to be excluded from the market. The length of the incubation period of our milk in the winter renders systematic testing of winter milk unnecessary.

We must, when considering infant diet, select a food hygienically prepared and procurable by poor and rich alike. Certain it is that among our tenement house population the summer diseases play greatest havoc. To this infant population, whose mothers are most often careless and uncleanly, a milk should be given, which has been hygienically prepared, which remains unchanged in quality, without the aid of ice, for twenty-four hours at least on a warm summer day, and which is inexpensive. The ordinary city milk procured early in the morning and sterilized as above within a few hours fulfills well these requirements. However, as to the sources of our milk supply, it is scarcely necessary that the dairies of the farmer be supplied with appliances which in agricultural usefulness can only be compared to the outfit of the amateur photographer. In proposing impracticable conditions for a large milk supply like that of New York we arouse ridicule. A healthy herd of cattle and the most ordinary cleanliness of hands and animals, as shown in our work, are all we can ask. The present methods of milk transportation, superior, we believe, to any in vogue in Europe, with watchfulness on the part of our authorities upon the ever-encroaching adulterations of the small city dealer, will, with the foregoing hints as to the preparation of the infants' food, protect our little patients.

I desire in conclusion to express my thanks to Dr. Koplik, under whose supervision and guidance this work was carried on.

The French Congress of Alienists and Neurologists.—We learn from the Moniteur médical that the sixth annual congress of the alienists and neurologists of France and the French-speaking countries will be opened in Bordeaux on the 1st of August, under the presidency of Dr. Joffroy, of the Paris Faculty of Medicine. The secretary general is Dr. E. Kégis, of No. 54 rue Haguierie, Bordeaux.

The Aetiology of Stricture of the Male Urethra, with Special Reference to Its Relations to Gleet.

(Concluded from page 139.)

Structures due to a chronic gonorrhoea comprise the great majority of strictures to be met with in the urethra. To hazard an estimate at the proportion of all strictures which would come under this class would be to make a statement which might be so inaccurate as to be misleading. The statement already given, that it preponderates numerically over all the other varieties of stricture taken together, certainly is a safe estimate even if it is indefinite.

A chronic gonorrhoea or a gleet may exist without the pre-existence of a stricture, but the variety of stricture under consideration can not exist without the precedence of a gonorrhoea which bears the relationship to the stricture of cause and effect.

The above assertion is in direct antagonism with the views taught by Otis, and is the vital point around which so much argumentative literature has centered. It is evident in view of its importance that the pathology of this variety of stricture is entitled to the closest consideration, and no apology need be offered for the introduction of subjects which at first sight may seem foreign to the one under consideration, but which nevertheless have a more or less direct bearing on it.

Gonorrhoeal infection of the urethra consists in the inoculation in the urethral mucous membrane of a specific micro-organism which tends to be self-limited in its duration, but which under favorable circumstances may continue to grow and invade the urethral mucous membrane for an indefinite period.

It is not material whether it is the gonococcus of Neisser or some other microbe yet unheard of that is the aetiological factor in the propagation of this widespread malady. Suffice it to say that it is a specific micro-organism capable of setting up an acute inflammation of the urethra which runs its course in from four to six weeks, ending in the majority of cases in recovery; but in a certain proportion of cases recovery does not ensue; the process becomes localized in certain areas of the urethra, and while of a lesser degree of intensity than the original acute inflammation, shows but little tendency to spontaneous cure.

This is the form of urethritis to which we apply the term chronic, and it is the variety which is the progenitor of the great majority of urethral strictures.

To Finger, of Vienna, must belong the credit of placing the pathology of chronic urethritis on an accurate and scientific basis. His post mortem investigations of numerous cases of chronic urethritis have such an important bearing on the subject of stricture and gleet that I will freely quote from his work on the subject* as follows:

"The hyperemia, serous swelling, and infiltration which are observed with the endoscope so often during life either disappear post mortem or become less recognizable.

"There are, however, numerous macroscopic changes. The epithelium exhibits changes which vary from slight opacity to considerable thickening and whitish discoloration; the latter condition often simulates superficial cicatrices. Losses of epithelium are much rarer than thickenings, and are usually superficial and isolated. I never found extensive erosions or ulcerations.

"The changes in the subepithelial tissue, the swelling, and infiltration which depend upon hyperemia, are indistinguishable on account of the disappearance of the hyperemia. Only one group of cases exhibited changes of the surface which were due to swelling. In circumscribed spots the surface appeared finely ridged, uneven, containing small nodules, whose size varied somewhat. These were undoubtedly granulations, as was shown by the microscopical examination.

"There are striking changes in Morgagni's lacunae. On section of the normal urethra these are invisible or appear as very fine dots. In a series of cases of chronic urethritis the openings are as large as the head of a pin, and with the surrounding parts may be elevated like a crater. In another group of cases the lacunae are absent, and they are replaced by milky-white nodules which are imbedded in the mucosa.

"With the unaided eye it is often impossible to distinguish cicatrices from simple epithelial thickenings. This is particularly true of ridge- and net-shaped, slightly elevated structures, which are formed in part by epithelium, in part by subepithelial connective tissue.

"Non-constricting, depressed, eccentrically retracted callosities are not infrequent. Examination shows that they are always very superficial and due to changes in the uppermost layers of the subepithelial connective tissue.

"There are numerous interesting microscopical changes. In a series of cases the epithelium still retains its normal arrangement, but the uppermost layer of cylindrical cells is loosened and in a condition of mucoid degeneration. The transition cells, consisting normally of one or two rows, are often spread over many rows. Numerous pus corpuscles are imbedded between the cylindrical and transition cells. Another interesting change is the transition of cylindrical into pavement epithelium. Three types of pavement cells may be distinguished:

"(a) It resembles that of mucous membranes with pavement epithelium—i.e., it consists of an undermost layer of cubical cells, several layers of polygonal cells, and an upper layer of pavement epithelium.

"(b) The epithelium is epidermoidal, consists of a lower layer of cubical cells, followed by several layers of polygonal or spindle-shaped cells analogous to the rete Malpighii; these cells constantly grow larger and flatter toward the surface.

"(c) The epithelium is like that over cicatrices, and consists of several layers of very flat pavement epithelium.

"This conversion of cylindrical into pavement epithelium, which causes a xerosis of the mucous membrane, is connected with the changes in the subepithelial connective tissue. Thus the first type of cells is found over recent round-celled infiltrations, the second type over older ones, the third form exclusively over firm connective tissue.

"The subepithelial connective tissue exhibits the most important changes, and is the site of the chronic inflammatory process proper. This consists of an infiltration of the connective tissue, which has a decided tendency to transformation into retracting connective tissue. In the more recent cases we find that the subepithelial connective tissue, sometimes only in the upper layers, sometimes extending even into the corpus cavernosum, contains a loose or dense infiltration, consisting of mononuclear and epithelioid cells, sometimes mixed with pus cells. This infiltration surrounds the lacunae and glands imbedded in the subepithelialoid tissue; hence it is also perilacunar and peri-glandular.

"In a group of cases the cellular infiltration contains numerous, evidently new-formed, very wide blood-vessels. These two factors—viz., the infiltration and the blood-vessels—give to the subepithelial connective tissue that papillomatous appearance, that mulberry-like condition of the mucous membrane in places which we described as granulations. The infiltration consists of round and epithelioid cells; as it grows older the spindle cells become more abundant, the interfibrous tissue becomes denser and firmer, and there finally results a tissue which resembles a cicatrix anatomically. It is not due to ulceration, but to chronic connective-tissue hyperplasia. The granulations which may have formed during the recent stage are flattened by the retraction, and a callosity results. This corresponds to the infiltration of the first stage; it is always circumscribed, sometimes located superficially in the uppermost layers of the subepithelial connective tissue, sometimes it extends deeply, even into the corpus cavernosum.

"The stage of infiltration and cicatrization may be complicated temporarily by exacerbation of acute inflammation and emigration of leucocytes.

"The lacunae exhibit changes analogous to those in the mucous membrane. The epithelium shows desquamation of the cylindrical cells, proliferation of the transition cells, transformation into pavement epithelium. The infiltration in the perilacunar tissue often raises the lacunae and dilates their lumen. If the infiltration in the connective tissue retracts, the lacunae will become atrophic and disappear. Not infrequently the outlet is first narrowed, and the lacuna is then converted into a little cyst filled with pavement epithelium.

"Littre's glands, which are situated in the meshwork of the corpus cavernosum, exhibit two kinds of changes. In one the change is periglandular; the small-celled infiltration of the subepithelial connective tissue around the excretory ducts of the glands draws them downward and surrounds the gland and its duct. The excretory duct also exhibits epithelial changes which imitate those found upon the free surface—viz., the three types described above. Special interest attaches to the second type, in which the epithelium resembles that of the rete Malpighii. This is developed excessively in the excretory ducts, even extends
into the body of the gland, pushes beneath the secreting glandular epithelium, and leads by compression to destruction of the acini. The secreting epithelium merely exhibits passive changes—viz., destruction by the periglandular infiltration, which penetrates into the network of the acini.

"Exacerbations of acute inflammation, with emigration of pus corpuscles, can also be demonstrated in the glands and their excretory ducts.

"In a number of cases the corpus cavernosum is entirely intact. It may also take part in two ways in the chronic inflammatory process.

"In one series of cases the chronic infiltration remains in the main superficial. It only enters the corpus cavernosum along the excretory duct and around the bodies of Littré's glands. This periglandular infiltration compresses not only the glands, but the adjacent spaces of the corpus cavernosum are also drawn into the retraction. The corpus cavernosum then appears to be traversed by an entire series of cicatrical connective-tissue bands.

"In another series of cases the chronic infiltration, which occupies the entire thickness of subepithelial peri-urethral tissue, also penetrates the corpus cavernosum; here it remains superficial or occupies its entire width. In the first stage of the small celled infiltration the trabeculae of the corpus cavernosum appear enlarged and infiltrated with numerous round (later spindle) cells. If this infiltration, which is always circumscribed, undergoes retraction, the mucosa and corpus cavernosum are converted into a firm, retracting callosity. These deep spreading callosities are the causes of stricture.

"Wasserman and Hallé (1891) have confirmed these findings, and we are therefore warranted in defining stricture as the result of chronic cicatrlic peri-urethritis and cavernitis, which complicate chronic urethritis.

"Hence we must distinguish in the pars anterior two forms of the chronic process: a purely mucous, superficial form, which results in superficial, non-constricting, eccentrically retracting cicatrices; and a second form, in which the process extends to the peri-urethral tissue and corpus cavernosum, and thus leads to stricture."

On page 144 of the same work there appears the following: "So long as the process remains localized in the mucous membrane, these are the symptoms which may persist for years. That such a chronic urethritis, situated solely in the mucous membrane, may heal as the result of recovery of the spot of infiltration by the formation of connective tissue and superficial cicatrices I have proved by post-mortem examination. When the process extends to the submucous tissue, to the corpus cavernosum, and the chronic infiltration heals by the formation of retracting connective tissue, a new and gradually developing symptom of a more serious significance is added to the clinical history—viz., narrowing or stricture."

The pathology of chronic urethritis, as portrayed by Finger, sheds considerable light on the formation of stricture. Many questions still remain unanswered, and there is still much that is obscure, but the recent advances made in this line of study give promise that urethral pathology will soon be established on an accurate and scientific basis.

The chief point of interest that the subject has is the relationship of granulations or granular urethritis to stricture. An effort will be made to prove that a granular urethritis is not only the forerunner, but the prime etiological factor, in the production of the great majority of strictures of the urethra, and by the same proof to demonstrate the fallacy of the theory, so generally accepted, that stricture bears a relationship to gleet of cause and effect.

It will be necessary, however, to enter somewhat in detail into the subject of granulations, and also, in so doing, avail ourselves of the results of investigations, not only in the urethra, but also in the conjunctiva, where we frequently find a similar condition present.

Granular urethritis and granular conjunctivitis are closely allied, not only in the source from which they are derived, but also in their pathology, symptoms, and course. A granular urethritis is the result of a gonorrhoeal infection of the urethra. This is so well recognized that it is no longer a subject for discussion, and may therefore be passed over without further mention. It is difficult, however, to explain why the gonorrhoeal virus should become localized to certain areas of the urethra to the exclusion of other areas which, to all appearances, are no better protected nor better able to resist the invasion of the micro organisms.

The analogy between granular urethritis and granular conjunctivitis has already been referred to, and, since the well-known course of the latter will be utilized to corroborate the statements concerning the less known course of the former, it may be advisable to establish their relationship at the outset.

Granular conjunctivitis is, in the vast majority of instances, derived by contact with a similar case of granular conjunctivitis. It is well known that a single individual with this disease may infect a whole community, as is sometimes witnessed in asylums, schools, and barracks. A case of granular conjunctivitis always gives rise by transmission to a similar conjunctivitis, but it is now generally recognized that this is not the only source of the malady, for it has been shown that a gonorrhoeal conjunctivitis may be followed, as in the urethra, by the formation of granulations, which in its turn may perpetuate the latter disease.

The following extract bearing on this subject is from Dr. Ernest Fuchs's "Text-book of Ophthalmology," page 77:

"Does any connection exist between trachoma and acute blennorrhoea?"

"These two diseases, which both originate in infection, are, of course, in their typical form very different from each other. Nevertheless, the chronic blennorrhoea which develops from an acute blennorrhoea is so similar to the papillary form of trachoma that these two can not be distinguished from each other with certainty either by the clinical examination of the eye or by anatomical dissection.

"We may advance the following hypothesis: Recent acute blennorrhoea when transferred to another eye produces acute blennorrhoea in the latter also. But if the acute blennorrhoea has already passed into the chronic form, its transfer to another eye is no longer an acute but a chronic..."
inflammation, which latter is trachoma. Different observations speak for the possibility of such a method of origin of trachoma. Goldziher reports an epidemic of trachoma in the school for the blind at Budapest, an epidemic which had been introduced by a newcomer, a boy who had lost his sight from acute blennorrhoea. Through him all the male and most of the female scholars became affected with trachoma, all possible forms of which, including the pure papillary, the pure granular, and the mixed, could be recognized.

"Sattler has observed the following case: A mother, who was affected with leneorrhea, gave birth to a child having acute blennorrhoea of moderate degree. The mother acquired a genuine trachoma by infection from her child. As she lived in a region perfectly free from trachoma, infection from any other source was excluded. Against such a connection, between chronic blennorrhoea following the acute form and trachoma, the objection has been raised that in the former disease granulations (lymphatic follicles) have never been observed. But this is not always the case. In the autumn of 1887, two girls, sisters, were admitted to my clinic, the elder of whom had acquired an acute blennorrhoea of the conjunctiva of both eyes as a consequence of her own leneorrhea. The younger sister had caught the infection from the eyes of the elder and likewise acquired acute blennorrhoea of both eyes. In her case this was not quite so severe in its onset, and, after the greatest violence of the inflammation had abated, papillary outgrowths developed in the conjunctiva tarsi, and numerous granulations in the folds of transition, so that there was presented a perfect picture of mixed trachoma.

"In many other cases besides this I have been able to observe the development of granulations in the folds of transition after acute blennorrhoea, and still more frequently have been able to prove their existence by the microscopical examination of excised portions of the conjunctiva.

"From what has preceded we may draw the following conclusions: There is but one kind of trachoma, which, however, appears under various forms. The ultimate origin of the disease is probably referable to the secretion of genitals affected with gonorrhea. This secretion produces in the human conjunctiva acute blennorrhoea, which passes into chronic blennorrhoea. The secretion of the latter produces in a healthy eye directly a chronic inflammation, trachoma, which then by a repeated process of transfer spreads of itself."

Premising that the relationship of granular urethritis and conjunctivitis has been satisfactorily demonstrated, and that we may fairly deduce from the one evidence to support the other, we are in a position to proceed with the pathology of the disease.

The first manifestation of a granular urethritis is a round-celled infiltration of the subepithelial tissues. This infiltration may be limited to the mucous membrane or it may extend deeper, invading the submucous and cavernous tissue. The infiltrating cells tend to become heaped in clumps directly under the epithelium. New blood-vessels penetrate the infiltration, ramifying in the subepithelial clumps, giving to the urethra so affected the florid, papillary appearance so characteristic of granulations.

At a later stage the infiltrating cells become transformed into spindle cells and ultimately are converted into dense retracting connective or cicatricial tissue, while pari passu the epithelium of the affected portion passes into the pavement variety.

The contraction of the cicatricial tissue gradually strangulates the exuberant vascular supply of the granulation tissue, the affected area becoming as anemic as it was previously plethoric. At the same time it gradually changes in color from florid to pale or pearly white. By this means Nature by a process of substitution cures the disease, for not only does the conversion of granulation tissue into cicatricial tissue obliterate the former, but in addition the virus or exciting cause of the granulations disappears and its further propagation is rendered impossible.

It should be borne in remembrance that the conversion of granulation into cicatricial tissue is a slow process, requiring months or even years for its completion, and may be more advanced at one part than another. Side by side may frequently be seen all gradations, from the florid papillary surface of recent granulations to the pale dense cicatricial tissue of the completed process.

While we can not but admire Nature's method of working out a cure in these troublesome cases, we must admit that this is an evidence that she sometimes bungles in her handiwork, for she relieves one malady by the substitution of another, often of more serious import—namely, the replacement of granulation tissue by cicatricial tissue.

It often happens that this is a matter of no importance, as when limited areas of the mucous membrane alone are involved, resulting in superficial callousities which do not produce an appreciable diminution of the urethral caliber. When the cellular infiltration involves not only the mucous membrane, but also the submucous and cavernous tissue, the resulting transformation into retracting connective tissue may produce serious changes in the lumen of the urethra, varying from slight coarctations to almost total occlusion. From what has been said about the analogy of disease as it appears in the urethra and conjunctiva, we would naturally infer that they would pursue a similar course—namely, the cure of the disease by its conversion into cicatricial tissue. This is just what happens in the conjunctiva, where the resulting cicatricial contraction frequently produces, as in the urethra, marked deformity of the affected parts.

Now that we have considered stricture and its causes, a similar though much briefer exposition of gleet and its causes will be necessary before we can establish in a satisfactory manner the relationship of these two diseases.

Gleet has been defined by Hunter, Cooper, and other authorities as an imperfectly cured gonorrhea. This definition deals with the cause of the disease, and is open to the criticism that it is scarcely broad enough in its scope, since there are undoubtedly cases of gleet that are not gonorrhreal in origin.

Gleet is a chronic muco-purulent discharge which escapes from the meatus as the morning drop, and is less
noticeable or may be absent during the day, when the urethra is frequently flushed during urination. The discharge in certain low grades of urethral inflammation may be mucous-purulent and scant from the beginning. The terminal stage of a gonorrhoea is also mucous-purulent, but we do not apply the term gleet to these cases unless they become chronic.

The constituents of the gleety discharge are mucus, pus, and epithelial cells, the proportion of each varying with the varying conditions of the urethra. An exudation of mucus free enough to escape from the meatus is not always pathological, as it may be witnessed in an otherwise healthy urethra under intense sexual excitement. This is, however, but transitory and has no relationship to gleet.

The proportion of pus cells depends somewhat upon the intensity of the inflammatory disturbance. In a general way, we may say, the more marked the inflammation the greater the proportion of pus cells, while the preponderance of epithelial over pus cells is an indication of the favorable progress of the disease. The frequent microscopical examination of the discharge is therefore of some value from a diagnostic point of view.

A gleety discharge is an indication of a low grade of urethral inflammation, although the absence of a visible discharge is not necessarily a proof of the absence of a localized urethritis. The inflammatory origin of gleet is universally conceded; the only debatable question that may arise concerns its source, whether from a catarrhal or a granular urethritis, or from ulceration of the mucous membrane. Repeated endoscopic examinations have shown the frequency and often the association of the two former processes, while the same method of examination has shorn ulceration of its terrors and relegated it to a very minor position in the category of urethral ills. We may, therefore, safely say that a gleety discharge has for its source certain areas of the urethra which are in a state of chronic catarrhal or granular inflammation, and that both these processes are frequently present at the same time, while gleet due to ulceration (by this term is meant ulcers of the urethra so large as to be easily perceptible on ocular inspection) is so rare that for all practical purposes it may be ignored.

It is unnecessary to go into further detail on the subject of gleet. Its relation to stricture, to which much of the foregoing has evidently led up, will next receive consideration. The relationship of stricture and gleet, according to Otis, is simply one of cause and effect. In the light of the pathology of stricture as shown in this article, the arguments on which this statement is based will not bear investigation. If gleet is a symptom or result of stricture it necessitates the priority of existence of the latter, but it has been shown that stricture tissue is in the great majority of cases the terminal stage of a granular urethritis, and it has been shown that gleet is one of the earliest symptoms of a granular urethritis; therefore the impossibility of establishing the priority of stricture is evident.

A stricture resulting from a gonorrhoea does not manifest itself until the lapse of months and often years after the inception of the gonorrhoea, but it is a matter of common observation that the gleety stage is usually well established in a much shorter period, all of which is contrary to what we should expect were the latter a symptom of the former. Were stricture the cause of gleet, we should naturally expect that in those cases that remain untreated the progressively increasing obstruction to the stream of urine produced by the continuous contraction of the stricture would in like ratio tend to aggravate the gleety discharge. On the contrary, it is a very general rule that the gleety discharge progressively diminishes and usually ultimately disappears, notwithstanding that the stricture may be more evident than ever.

Even the most ardent disciples of Otis must concede what from their standpoint must seem inexplicable—namely, that a gleet is more commonly associated with those recent coarctations of slight degree called strictures of large caliber, than with the long-standing strictures of small caliber. This can be readily explained when we consider that the conversion of granulation tissue into cicatricial tissue obliterates the former, so that when cicatrization is complete the granulations with their gleety manifestations have disappeared.

Another argument that may be adduced to support the above is the fact that traumatic strictures are not necessarily associated with gleet at any stage of their formation, because this variety of stricture has not, as an etiological factor, a preceding granular urethritis.

The genito-urinary surgeons who maintain the dependence of gleet upon stricture have unfortunately made the mistake of placing the cart before the horse, or, to put it more accurately, they have placed two results of the same disease in the false relationship to each other of cause and effect. What is gleet but the mucous-purulent discharge resulting from a chronically inflamed urethra? What is stricture but the connective tissue transformation of the cellular elements of a granular urethritis into cicatricial tissue?

Even the arguments brought forward by Otis to prove his own teachings may be turned against him and made to tear down the very fabric they erected. An analysis of the reasons for holding the original views promulgated by Otis, and still more or less closely adhered to by his followers, can not but be, in the light of recent pathology, both instructive and interesting.

Otis bases his arguments to support his theory that stricture of the male urethra will create or perpetuate a gleet on the supposition that the stricture acts as an impediment to the passage of the urine.

No one will deny that a well-defined stricture, say fifteen millimetres or less, will interfere with the passage of a stream of urine; but those are the kind of strictures that are least often accompanied with gleet. The variety of stricture which is most frequently accompanied by gleet is the stricture of large caliber which does not obstruct the stream of urine.

To appreciate what Otis considers as coming within the limits of stricture, it is only necessary to glance at the records of his own cases, for which he has performed urethroty. We shall see frequent illustrations of strictures ranging from thirty to thirty-five millimetres. In his work on stricture of the male urethra he has tabulated the
number and size of the strictures in a hundred and seventy-four cases as follows:

</table>

The total number of strictures in this table is four hundred and twenty-one, of which three hundred and twelve, or about seventy-five per cent., range from twenty-four millimetres upward, and twenty-six per cent. are thirty millimetres and upward. Many of the strictures of thirty millimetres and upward are only from one to four millimetres smaller than the given size of the urethra. Without stopping to consider the propriety of calling these strictures, we must deny most emphatically that they would interfere with the passage of a stream of urine by acting as a point of increased friction, for even the most capacious urethra rarely emits a stream of urine larger than a No. 25 sound, and a fair average of the size of the stream of urine may be given as about eighteen millimetres in circumference. This estimate, however, is given by the writer simply from observation and not from actual measurement.

It is difficult to comprehend how a stream of urine ranging from fifteen to twenty millimetres can be retarded in its passage through a urethra which does not manifest points of constriction until it is dilated to a size of thirty millimetres or upward. There is a very general misapprehension of the pressure exerted against the urethra in the passage of a stream of urine. It is generally supposed that where there is an obstruction to the passage of a stream of urine, as in stricture of the urethra, there is an increased pressure against the urethral wall at the constricted area. The writer remembers hearing a prominent professor of surgery advocate before an international medical congress the method of dilating strictures by instructing patients to close the meatus and resist the passage of the stream of urine. It will readily be conceived how much worse than useless is this method of treatment when we consider not only that the strictured area is the least yielding part of the urethra, but also that a stream of urine exerts least pressure against the strictured area. Let the urethra, for the sake of illustration, be represented by the tube a a in Fig. 13, s s representing a stricture.

It will be found that in the passage of the stream the least pressure will be exerted against the urethral walls at the strictured area s s, as is shown by the height the water rises in the tubes c, d, e, f, g, or in the water-pressure line b b.

Before concluding, the following deductions on the causation of stricture and its relations to gleet may be drawn from the foregoing:

1. Strictures are more frequently caused by gonorrhoea than all other causes combined.

2. Strictures due to gonorrhoea are secondary to the formation of granulation tissue. The latter is caused by the long-continued growth and localization in certain patches of the urethra of the gonorrhoeal virus.

3. Granulation tissue in its early stage is one of the most common sources of gleet. Its ultimate conversion into cicatricial or stricture tissue destroys its glety manifestation, so that by the time the process of cicatization is complete the glety discharge has disappeared.

4. The depth to which the granulation tissue has invaded the urethra determines the degree of the stricture. If it is confined to the mucous membrane, superficial callosities are formed which do not obstruct the urethral canal. If the cavernous tissue is invaded, true stricture is produced.

5. Gleet is an early manifestation while stricture is a later manifestation of granulation tissue, but owing to the process of cicatization being only partially completed they are usually associated with each other. Complete cicatization obliterates the former and perpetuates the latter.

6. The relationship of stricture and gleet is therefore not one of cause and effect. They are only related in so far that they may be derived from the same source. The evidence produced that stricture may cause or perpetuate a gleet is not supported by recent pathological investigation.

The cure of a gleet depends on the removal of its cause. The importance of establishing the cause is therefore evident. A consciousness of the enormous amount of unnecessary urethral surgery that has been undertaken for the removal of fancied or real strictures as a means of treating gleet has impelled me to publish the results of my convictions in the hope that it may be instrumental in directing attention to the true source of a most annoying malady—stricture of the urethra—and in establishing its true relationship to its congener, gleet.

The West End Medical Society.—At the last meeting, held on February 24, the following officers were elected: Trustees, to hold office for one, two, and three years, respectively, Dr. Dawbarn, Dr. Ilasey, and Dr. E. J. Ware; president, Dr. F. M. Crandall; vice-president, Dr. Le Roy Brown; treasurer, Dr. H. G. Myers; recording secretary, Dr. F. J. Brockway; corresponding secretary, Dr. E. Harris; pathologist, Dr. J. S. Ely.
THE BRYSON SYMPTOM IN EXOPHTHALMIC GOITRE.

WITH A REPORT OF FORTY CASES.

By HUGH T. PATRICK, M.D.,

PROFESSOR OF NEUROLOGY IN THE CHICAGO POST-CLINIC.

Five years ago Dr. Louise Fiske Bryson† first called attention to a condition in Graves’s disease that has since been called the Bryson symptom—viz., diminished chest expansion or vital capacity. She cites it as one of the “distinctive, fixed conditions” prevailing in this disease which “afford the only rational basis for prognosis.” Other fixed conditions are not specified and no measurements or cases are given. Dr. Greece M. Hammond‡ considers it “of the greatest importance in regard to the prognosis” and “also of assistance in locating the seat of the lesion.” He says further: “Dr. Bryson states that where the expansion is found to be reduced to half an inch or less the termination of the case is invariably fatal.” He found the symptom present in six of the eight cases reported in his paper, and as recovery took place the expansion increased. Dr. A. B. Pope§ has reported a case of exophthalmic goitre in a man with chest expansion of an inch and a half, and in the discussion Dr. E. Le Fevre said the symptom was “owing to some nervous influence similar to that which gave rise to the rapid heart action.”

Three years after her first paper Dr. Bryson∥ resumes the theme, giving particular prominence to the respiratory symptoms, and emphasizing especially diminished chest expansion, but she seems to have receded somewhat from her former positive position as to its pathognomonic importance, as of twenty cases the Bryson symptom was present in only thirteen. She considers the disease, however, to be “a disorder of nutrition respiratory in its first manifestations,” and even makes this assumption the foundation of a therapy consisting of a series of respiratory gymnastics executed by means of Taylor’s respirator. These views have been quoted at home and abroad,* and the Bryson symptom would seem to be about to take its place among the important signs of Graves’s disease as bearing upon the diagnosis, prognosis, pathology, and treatment. Hammond,† indeed, distinctly calls it the fourth cardinal symptom, a distinction, by the way, which belongs to Marie’s symptom—tremor.

At the time when Dr. Bryson’s first article appeared I had under observation a case of exophthalmic goitre which I measured several times, finding the chest expansion not materially diminished. After this I measured a number of cases, finding the expansion sometimes diminished and sometimes about normal, and I presently noticed that diminished expansion seemed to go with a diminution in general vitality and muscular strength. I finally, then, began comparing the chest expansion with the hand grasp as recorded by the dynanometer, this affording the most convenient, if only approximately accurate, index of the general muscular condition. It is the result of these measurements that I wish to present. I may premise that only well-developed, in a measure typical, cases are comprised in this report, no formes frustes being included, and that the diagnosis was in every instance confirmed by some well-known neurologist. I have therefore deemed it unnecessary to lengthen my paper by giving the symptoms of each case in detail. With the exception just noted, the cases have not been selected, but embrace all that I was able to measure from November 1, 1892, to May 1, 1894.

The patients were all women, and it may be worthy of note that of some sixty cases seen since 1891 only two were in men.

It is a matter of common remark that no two observers take the chest expansion exactly alike, so that figures obtained by different persons can not be compared with confidence. To form a safe basis for comparison, therefore, I took the chest expansion and dynamometric measurement of twenty-eight women who came to the dispensary for

Goitre from youth.

No treatment the past year; as treatment the two preceding years almost cured her. Much worse since influenza two years ago. Developed after hemiplegia. Cerebral apoplexy.

Locomotor ataxia for the last ten years. Stigmata of hysteria; right hand excluded from estimate, as low figure is due to psychic inhibition.

Was much worse eight months ago; all symptoms were more pronounced.

Patient thinks an operation on the nose for catarrh aggravated the disease.

Has had goitre ten years. Nervous and irritable four years. All symptoms of Graves's disease five weeks, following failure in business. Complicated with hysteria. Has imperiove ideas. March 3d, feels much better. Symptoms aggravated by operation on uterus two years ago. Difficult labor seven months ago, since which time is nervous and anemic; is now two months pregnant; all symptoms of Graves's disease six weeks. Following confinement eleven months ago.

Following a fright; sister has same disease, and is much worse. Following influenza; thyroideectomy thirteen months ago, with great improvement.

Following fright.

Epilepsy; much worse the last three years. After inception cured (?) by rest, etc.; recurrence one year ago.
various ailments, selecting those whose troubles would not, in my opinion, affect the result. These are presented in Table II.

**Table II.—For Comparison.**

| 4/8 | 56/56 |

I am well aware also of the varying results given by the dynamometer, and I do not allege absolute accuracy for my figures or wish to too sweep the deductions from them, but all measurements were taken by myself as nearly a uniform manner as possible, and sources of error excluded as well as might be.

It will be seen that the average chest expansion in the forty cases of exophthalamic goitre is 43 centimetres and the hand grasp 43:75 kilogrammes; in the twenty eight other cases, 48 centimetres and 56:36 kilogrammes respectively—that is, the expansion in Graves's disease is diminished half a centimetre, or ten and a half per cent., the hand grasp 12:61 kilogrammes, or twenty-two and two fifths per cent. In other words, the grasp is diminished more than twice as much as the expansion. It may be contended that the average expansion of the twenty eight women used for comparison is not up to the normal, and I think this may possibly be true, but I also think they make a far better basis for comparison than statistics of measurements taken by some one else whose methods would doubtless differ in some degree from mine, and consequently whose results, other things being equal, would differ from mine. Further, these measurements were made in the same dispensary which furnished the majority of the cases of Graves's disease,* and the subjects are fairly representa-

tive of the class of patients furnishing the material for this report, and, as before mentioned, the pathological conditions in these women were not such as to materially affect chest expansion or hand grasp. But even supposing that the expansion of the twenty-eight might be materially below the normal, we could not suppose in all these various cases a condition which would affect chest expansion to the exclusion of other muscular action, including hand grasp, and as we find that the hand grasp in Graves's disease is diminished twenty-two and two fifths per cent, and the expansion only ten and a half per cent., the natural conclusion would be that if one of these two is pathognomonic of this malady it would be the weakened grasp and not the diminished chest expansion, an assumption I would not for a moment entertain. Again, we find of the forty cases twenty-six with an expansion below the average of the twenty-eight, while thirty show a diminished grasp.

Could we take accurate dynamometric measurements of the lower extremities and of the pelvic muscles, I have no doubt we should find an equal falling off. Many of these patients complain of a sudden "giving way of the legs," and placed in the recumbent posture show their muscular weakness in the manner of rising.

A woman now under observation, not included in this report, is a case in point. It is not what could be called a very severe case; she does her own housework, gets about very well, hand grasp and chest expansion only slightly diminished, and yet she rises from the supine position much like a patient with idiopathic muscular atrophy; that is, she first raises the trunk by means of the arms till she rests on her elbows; then, again, by help of the arms and with a peculiar wriggle or writhing movement to bring accessory muscles into play, she brings the trunk to the perpendicular; the erect position is then attained, with manifest effort, by turning round and pushing herself up with her hands first on the floor and then on her thighs or adjacent objects.

I think the diminished power of convergence often observed, as well as the occasional affection of the laryngeal muscles, is quite analogous to these other findings, and is simply a part of a general myasthenia, sometimes affecting one set of muscles more, sometimes another.

I find, further, that many of these cases show a rapid and marked falling-off in both chest expansion and hand grasp on repeated effort. Thus either may diminish one half after three or four trials in rapid succession, and in a general way the decrease affects both and is proportional to the debility.

The idea that the diminished chest expansion is simply part of a diminished vitality or energy is borne out by the history of individual cases. I have generally found that as the patient improves in general tone the expansion increases (and vice versa), although not necessarily in the same ratio, and that the grasp goes with it hand in hand. But as the diminished hand grasp shows the larger percentage in the table, so here it is apt to show the larger fluctuations, which would seem again to indicate that it is the more delicate index of the two. These facts are well illustrated by Case III. The rule, however, is not absolute, and

* Professor Mendel's Poliklinik, Berlin.
Case XXXVII is a striking exception in the first two examinations.

The only one of my patients (Case III) who ever showed an expansion as low as half an inch (1.25 cm.), indicating, according to Dr. Bryson, an absolutely fatal termination, had, four months later, gained over twenty pounds in weight, and was better than at any time during the six months she was under observation.

I think, then, we may conclude that the Bryson symptom, although present in many cases of exophthalmic goitre, is in no wise pathognomonic of this affection, or even an important sign; that it has no special significance in relation to the prognosis, pathology, seat of the lesion, or treatment, and should be relegated back to the comparative obscurity of an individual in a large community of manifestations which all depend alike upon the general state; a state which makes the French designation of the disease, exophthalmic cachexia, quite as appropriate as any other.*

* Venetian Building.

THE VALUE OF GUDE’S PEPTO-MANGAN IN THE TREATMENT OF ANEMIA.

By HUGO SUMMA, A. M., M. D.,
PROFESSOR OF PATHOLOGY, PATHOLOGICAL ANATOMY, AND BACTERIOLOGY,
PHYSICIAN TO THE EVANGELICAL DEACONESS HOSPITAL; PATHOLOGIST TO THE REBEKAH HOSPITAL.

The year 1893, with the publication of the results of very careful chemical investigations of the conditions of the blood in various diseases, especially those of the blood itself by Professor von Jaksch (1), the well-known author of the Handbuch von Clinical Diagnosis, marks a new era in our understanding of the various anemic processes. Our former vague knowledge of these conditions was molded into definite shape and form chiefly by his successful effort to elucidate all the characteristic features common to the various forms of anemia. He was thereby enabled as the first one to give a definition of this, up to this time, so pliable and undoubtedly much-abused term, anemia.

Anemia, in the broadest sense of the word, includes all those processes characterized by a decrease in the amount of albumin and by an increase of the liquid part of the blood; in other words, hypoblinemia and hydramia are conditions present in all forms of anemia, and this holds good not only in cases of primary anemia, like leukemia and chlorosis, but also in all so-called secondary anemia.

This discovery enables us to understand the hitherto empirical fact that the treatment of anemia requires not only or exclusively the administration of iron, but that all the metabolic processes, especially the introduction and assimilation of albuminous substances, must be increased, should the treatment be followed by success. But just this part of the treatment is exceedingly difficult, since one of the most constant symptoms which we meet with in the various forms of anemia is a more or less high degree of anorexia. This anorexia completes the “circulus vitiosus” so frequently observed in clinical pathology—a circulus vitiosus which must be understood in each individual case in order to be amenable to successful treatment. For it is evident that a continuous anorexia will lead to insufficient nutrition, to subnutrition, thereby constantly increasing the condition of hypoblinemia.

The anorexia is, however, a natural sequel of this abnormal condition of the blood, in consequence of which, at least in the greater number of cases, the secretion of hydrochloric acid is decidedly diminished (2).

In the treatment of these cases, therefore, we must constantly bear in mind the condition—hypoblinemia. In order to facilitate the increase of albumin in the blood, notwithstanding the anorexia already existent, its administration in the form of easily assimilated peptones would be most rational.

Prompted by this thought, I began in the spring of 1893 to make use of Dr. Gude’s preparation, known as pepto-mangan, in most all cases of anemia that came under my observation, with the exception of those accompanying or following chronic infectious diseases, such as tuberculosis, or of malignant tumors, such as cancer, etc. I collected from my clinical record thirty-four cases. The greater number of these were closely observed, not only as to the influence of the remedy upon the subjective symptoms, but also as to its effects upon the blood by careful examinations which I carried out with the aid of Gärtner’s hemokrit (3).

This excellent instrument, which requires the use of Professor Gärtner’s Kreisel (spinning top) centrifugal machine, enables, in a very accurate manner, a determination of the volume percentage of the red blood-cells within about ten minutes.

I prefer this method of determining the efficacy of a remedy against anemia to the old method of counting the red blood-corpuscles.

Although, generally speaking, the number of the red blood-corpuscles bear a certain proportion to the volume percentage, yet it would be wrong to identify both. In blood diseases especially, the knowledge of the volume percentage is undoubtedly of great importance.

During the above-mentioned period I observed neither cases of leukemia nor of pernicious progressive anemia.

The thirty-four cases I treated with pepto-mangan were partly cases of chlorosis and partly secondary anemia, occurring chiefly after subacute malaria and typhoid fevers. Of these I select six as paradigmas, as it were.

Two of these were cases of chlorosis and four cases were secondary anemia:

Case I.—Miss A. S., aged eighteen years; chlorosis rubra; oligoeytheremia and oligochromemia; palpitation of the heart; frequent pulse; coated tongue; factor ex ore; constipation; irregularity in menstruation; easily fatigued; muscular weakness.

At the beginning of treatment, thirty-per-cent. volume; eight days later, thirty-eight per cent.; at the end of the fourth
week, forty-eight per cent. Great improvement, slight catama-
ernal disturbances only remaining.

Case II.—Miss E. B., aged sixteen years; paleness of skin
and visible mucous membranes; slight dyspnea, short breath;
oligoecytanmia and oligochoeytanaemia; palpitation of the heart;
tachycardia; anemic systolic murmurs, increased second pul-
onary sound; disturbances in menstruation; tired feeling;
sleepy condition.

At the beginning of treatment twenty-eight-per-cent. volume
of red blood-corpuscles were found; increased within eight
days to thirty-five-per-cent. volume; after four weeks, forty-
five per cent. Apparently complete recovery.

Case III.—R. T., aged five years; first treated for subacute
malarial disease extending over two months. Patient had greatly
deceased in weight. No appetite, retarded action of the bowels;
great pallor; continuous tiredness and weakness. On examin-
ing the blood, I found thirty-five-per-cent. volume of red blood-
corpuscles; eight days later they increased to forty-two per
cent.; at the end of four weeks to forty-eight per cent. Com-
plete recovery.

Case IV.—Mrs. A. R., aged twenty-eight years; suffered from
chronic malarial disease. Mother of two children, the
youngest four months old. Fair advanced case of secondary
anemia. Patient unable to do any kind of work. Digestive
disturbances. Determination of volume of red blood-corpuscles
showed thirty-two-per-cent., which increased within eight days
to thirty-eight per cent., and finally reached forty-five per cent.
Great general improvement.

Case V.—Mr. T. K., aged nineteen years, butcher. Ty-
phoid fever of moderate severity; during this disease para-
ritism of right thumb followed by lymphadenitis axillaris.
Slow recovery. Anemic condition very pronounced. No
prominent single feature. General languor. Shortly after pa-
tient had entered the period of convalescence the blood ex-
hibited twenty-six-per-cent. volume of erythrocytes; fourteen
days later an increase to but thirty-two-per-cent. volume; after
four weeks, forty-six per cent. Patient now in very good
health.

Case VI.—Mr. T. M., aged twenty-four years, saloon keeper.
Ulcus ventriculi rotundum chronicum for seven years. Intense
localized pains with frequent attacks of vomiting, sometimes of
pure blood. Hyperchlorhydria of moderate degree, 3/2 per cent.
Quite pronounced anemia. After recovery from primary dis-
ease the volume of his red blood-corpuscles amounted to thirty-
six per cent.; eight days later we found forty-per-cent. volume;
finally, fifty-per-cent. volume. Patient up to this time was free
from symptoms of any kind.

In conclusion, I should like to state that similar good
results were obtained in the remaining twenty-eight cases.
It is especially worth while mentioning that no bad after-
effects could be detected. In this connection I call special
attention to the absence of constipation that could be traced
back to the use of this preparation.

The dose varied from a teaspoonful to a tablespoonful
three times a day an hour after meals, either in sherry or
milk, according to the individual case, especially according
to the condition of the digestive organs.

THE ETIOLOGY AND TREATMENT OF
SPASM OF ACCOMMODATION.

BY GEORGE F. SUKER, M. D.,
TOLEDO, OHIO.

The spasm of accommodation is frequently, if not gen-
really, brought about by the abuse and excessive use of the
muscles of accommodation under unfavorable circumstances.

The causes of spasm may be enumerated as follows:
1. One of the most frequent causes is working with
minute objects, which can only be seen distinctly when
brought closer to the eye than the normal punctum proxi-
mum. Especially is this so when the work is carried on by
scant illumination for any length of time—e. g., reading
fine print during twilight hours, writing, or doing fine
needlework. For the same reason, in order to obtain a
larger retinal image, amblyopes and astigmatics hold their
objects so near their eyes as easily to subject themselves
to spasm of the accommodation. Hyphoric refraction at
all times calls forth an excessive employment of accom-
modation when no glasses are worn or when the glass
worn is too weak. It is for this reason that we so often
find all kinds of spasm of accommodation among the
hyperopes. This is especially prominent among students,
the majority of whom are hyperopic. These often wear no
correcting glasses, thus leaving a good share of the range
of accommodation latent, which invariably produces a spasm.

2. Irritation of the ciliary muscles, especially of the
ciliary nerves, often gives rise to various forms of spasm.
The progressive form of myopia may be mentioned in this
connection as producing spasm, also incopt glaucoma.

3. Insufficiency of the recti interni is another cause of
spasm. At the same time insufficient externi recti are
prone to produce more or less spasm of accommodation;
for with insufficient interni recti an effort far above the
normal is called for to achieve the necessary convergence
to maintain the point of fixation, and this calls forth too
great a strain on the power of accommodation. This is so
from the fact that convergence and accommodation, up to
a certain point, are closely related actions. This state of
affairs is prominently brought forth in myopes.

4. Furthermore, various kinds of traumatisms are very
apt to produce spasm of the accommodation. Foreign
bodies in the conjunctiva or in the cornea frequently main-
tain a spastic myosis or accommodation for the near point.
The spasm here is due to reflex irritation.

5. Morphine and calabar bean are cited as specific causes
of certain forms of spasm. Even a spasm of the orbicularis
palpebrarum has been credited by von Graeffe with having
caused spasm of the accommodation. How spasm of this
muscle could produce a similar condition of the muscle of
accommodation is rather strange indeed.

6. The effort to overcome diplopia, especially in recent
cases, may give rise to spasm of accommodation. This
occurs more frequently when the diplopia is due to insuffi-
cient muscles than when it is due to other ocular defects.
7. At times, on the instillation of homatropine, a spasm of accommodation may arise. This usually occurs when five or six applications have been made, and may be accounted as a reflex spasm. This form is of short duration, and can be overcome easily by the continuance of the homatropine or by the use of the ordinary sulphate of atropine, preferably the latter.

8. Certain hyperesthetic conditions of the retina may bring about spasm of accommodation. This is purely of a reflex nature. It occurs in cases where the retina is over-sensitive to diffusion circles. The retina is the regulator, as it were, of the accurate image formation, and the inaccuracy dependant on the diffusion circles is the point of irritation giving rise to a reflex spasm.

9. Finally, inflammatory conditions of the conjunctiva, cornea, or sclera are capable at times of producing spasm. This is found mostly among those of a highly strong nervous system, in whom the slightest irritation is sufficient to produce a spasm of almost any muscle. The rarer forms of spasm are attributed to epilepsy, hysteria, and disturbances of the central nervous system. Irritation of the cilio-spinal center may produce the same condition spoken of. Then, too, certain brain lesions are credited with the production of spasm of the muscle of accommodation.

The treatment of spasm of accommodation is as follows: 1. If possible, remove the exciting cause; this certainly is of prime importance. 2. Avoid the continual straining of the eyes; advise frequent intervals of rest if work can not be entirely suspended. 3. Obtain the best illumination possible; ameliorate the too intense light by wearing smoked lenses. 4. Treat any insufficient muscle; relieve all irritations. 5. The spasm which produces a certain amount of latent hyperopia is to be overcome by prescribing suitably adjusted convex glasses. The same may be said of myopia and astigmatism. It is not absolutely necessary to correct the entire amount of hyperopia, for a certain portion may remain uncorrected without causing any evil results. 6. In myopes, when the spasm is due to irritation of the ciliary muscle, it can be overcome by local leeching and insistence upon absolute rest for the eyes. 7. The mainstay in the treatment is the sulphate of atropine, which is sure to allay the spasm as long as it is instilled, and in the majority of cases gives a cure, providing the former exciting causes are to a great extent done away with. A stronger solution than usual is employed, for it takes a longer time for it to act on a spastic muscle than on a normal one. One may employ it as strong as gr. j. to 3 j. or 3 j. of water, two or three drops to be instilled three or four times daily. 8. In traumatic cases make use of antiphlogistic measures. Remove foreign bodies if there are any present. 9. The constant galvanic current is much lauded in certain cases. At times a rapid local abstraction of blood may materially reduce the spasm for the time being. At no time should we forget to make use of constitutional treatment. If atropine produces untoward effects, sulphate of daboisine may be used in its stead, though it is not so reliable as the former.

Upon the whole, the treatment of spasm of accommodation is satisfactory both to the patient and to the physician.
Fremasons of North Connaught, calling on medical men who are also members of the order to contribute to a fund for building a Memorial Masonic Hall in Carrick-on-Shannon, the late Surgeon-Major Parke’s native town, as a memorial of that distinguished officer. In the same issue of the Lancet there is an editorial notice of a paper recently read by Mr. R. F. Gould before the Quatuor Coronati Lodge, entitled The Medical Profession and Freemasonry.

It appears from the Lancet’s analysis that Mr. Gould, who is not himself a medical man, has been investigating the relative activity of men of various callings in life with regard to Masonry, and that as the result of his researches he maintains that “it is by the influence of brethren who have been, or are, practitioners in medicine or surgery, more than to the members of any other single profession, that Freemasonry has been shaped and molded into the form, or perhaps it would be best to say the system (or set of systems), in which we now possess it.”

It seems that the Grand Lodge of England was established in 1717, and Mr. Gould says of it: “The Duke of Montague accepted the Grand Mastership in 1721, and the society rose at a single bound into notice and esteem. The first of our ‘Noble Grand Masters’ was a Fellow of the Royal College of Physicians (as was also the fourth of the series, the Duke of Richmond). The first Deputy Grand Master was Dr. John Boile, 1721; and the first initiate—after a Masonic torpor of some duration—was Dr. William Stukeley, whose admission took place in the same year.”

Among the individual physicians and surgeons of eminence in the British Empire who have figured in Masonry in modern times, the Lancet mentions the following, taken from Mr. Gould’s paper: Sir F. C. Daniel, R. T. Crucefix, John Havers, Thomas Joseph Pettigrew, Henry Hancock, J. Cooper Forster, Sir Erasmus Wilson, Alfred Meadows, W. Rhys Williams, Edward Jenner, Sir William Ferguson, and Sir James Y. Simpson.

The Lancet thinks it probable that there is hardly a lodge in England that does not include a doctor among its members, and adds that most of the London lodges have many medical brothers on their rolls. We think that equivalent statements would hold good of the United States; certainly it is not uncommon to see excellent Masonic work done by doctors.

Mr. Tait wrote to Dr. Cushing to ask what the facts were to which he had alluded. In reply, Dr. Cushing renews a scandal to the effect that Mr. Tait had seduced one of his nurses, and then, after having pledged himself to support the illegitimate child of which he owned to being the father, refused after a time to continue such support. Mr. Tait then wrote back denying the whole story and impugning its relevance. In the course of this letter Mr. Tait says:

“As to the story, it is a lie, or rather a tissue of lies, from beginning to end. Two women, sisters, entered into a scheme to blackmail me; one a nurse dismissed for insubordination, and one on whom I had done ovariotomy, and they laid claim to £16,000 as hush money. They never got a stiver of that money, and the case never came to trial for the reason that you will see in the published account of it which I inclose. The case never came to trial, never a scrap of information appeared in the public press, much to my discomfort, but the plaintiff’s story was spread abroad as a means of coercing me to pay hush money, and chiefly by members of my own profession residing in London. I stood firm to fight, as, unfortunately, too few men placed as I was do. The plaintiffs traded on the belief that a man in my position and as rich as I was would pay up rather than have my name tarnished. But I would have spent my last shilling, and my wife would have sold her wedding ring, before I would have been bleed in such a way. The case collapsed after nearly two years of legal dodging, and I never had an opportunity of proving the utter falseness of the charges made against me. Your informant may not have known this, but I suspect he did. Dates would prove this.”

Mr. Tait inclosed a photographed copy of the woman’s retraction, duly witnessed, as follows: “I unreservedly withdraw all statements and suggestions at any time made by me or on my behalf that you ever assaulted me or took advantage of me in any way while I was under the influence of liquor or under any other circumstances. And I also unreservedly withdraw all other charges, imputations, and reflections at any time made by me against you.”

Dr. Cushing, thereupon, as in honor bound, gave Mr. Tait the name of his informant, who turns out to be Mr. Ernest Hart, the editor of the British Medical Journal, now in India, and loyally offered to make any apology that Mr. Tait might require, and to give his testimony, if necessary, even in an English court. When Mr. Hart gets back to London we may perhaps be told how such a monstrous scandal got afloat.

**MINOR PARAGRAPHS.**

**THE "DEVELOPMENT" OF INSANITARY CONDITIONS.**

The bill lately introduced into the House of Representatives by Mr. Bartholom, providing for the appointment of a commission to inquire into the subject of the pollution of rivers and other sources of water supply in cases in which the health of the people of more than one State may be endangered—this bill seems to be meeting with the very general approval of sanitarians, and doubtless its enactment would be a wise and beneficent measure. One of the sections, however, provides...
that at the next session of Congress the commission shall submit such suggestions as may seem desirable for the purpose of remedying any insanitary conditions that have been "developed" by its work. Surely this is not what the framers of the bill meant, for he can hardly intend that the commission shall go into the business of developing insanitary conditions; he has simply lapsed into sloppy English.

"MEDICO-LEGAL MEDICINE."

To judge by the heading of an address published in the Medical Reporter, of Calcutta, in the number for January 1st, this somewhat pleonastic phrase figured in the title of one of the sections of the recent Indian Medical Congress, but we take it for granted that the heading was so printed by our contemporary only by oversight.

ITEMS, ETC.

The Society for the Relief of Widows and Orphans of Medical Men of New Jersey was incorporated in 1882, and we learn that it has continued to grow both in influence and in membership. Since its organization 214 physicians of the State have become members, of which number 22 have died and 25 have been dropped for various reasons, leaving at the present time 191 active members. The permanent fund amounts to $1,388.42, and it is intended to allow eventually small annuities to widows and minor children in cases of need. The amount already paid to the families of deceased members amounts to $2,478. The total cost of conducting the affairs of the society during the past year was $19.67.

A Lady Bacteriologist.—It is announced that Dr. Anna Williams has been appointed an assistant on Dr. Biggs's staff in the service of the Health Department of the City of New York.

Military Duty and the Professions.—The Christian Register says: "Dr. Baxter, examining surgeon during the civil war, in tabulating the results of his examinations, shows that, out of every 1,000 clergymen examined, 954 were unfit for military duty; out of every 1,000 journalists, 740; of physicians, 670; of lawyers, 544; while of farmers only 550 were thus disqualified."

The Late Dr. Alfred L. Loomis.—The secretary of the Medical Board of Bellevue Hospital has sent us the following, dated February 3, 1895:

"As instructed by the Medical Board of Bellevue Hospital, I forward to you the following resolutions:

"At a special meeting of the Medical Board of Bellevue Hospital held January 24, 1895, to take action on the death of Professor Alfred L. Loomis, M.D., LL.D., the following resolutions were entered on the minutes of the board:

"Resolved, that by the death of Dr. Alfred L. Loomis the members of the medical board lose a faithful and respected associate, the profession a brilliant and honored member, and the people a wise and vigilant public servant."

"Resolved, that the members of the medical board sympathize most deeply with his family in their sad bereavement."

"Resolved, that these resolutions be sent to the family and be published in the secular and professional press."

Army Intelligence.—Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from January 20 to February 2, 1895: Murrin, Edward R., Captain and Assistant Surgeon, is granted leave of absence for twenty-one days, to take effect upon being relieved from duty at Fort Warren, Massachusetts.

HEYL, Ashton B., First Lieutenant and Assistant Surgeon, is relieved from duty at Columbus Barracks, Ohio, and ordered to Fort Thomas, Kentucky, for duty.

LAUTERDALE, John V., Major and Surgeon, will be relieved from duty in the Department of the East, to take effect upon the expiration of his present leave of absence, and will then report for duty at Fort Omaha, Nebraska.

TILTON, Henry R., Lieutenant Colonel and Deputy Surgeon General, is relieved from duty at Fort Omaha, Nebraska, and will report in person to the commanding general, Department of Dakota, for duty as medical director of that department, relieving Byrne, Charles C., Colonel and Assistant Surgeon General. Colonel Byrne, on being thus relieved, will report to the commanding general, Department of the East, for duty as medical director of that department.

STILES, Henry R., First Lieutenant and Assistant Surgeon. The extension of leave of absence granted on account of sickness is still further extended two months on surgeon's certificate of disability.

Naval Intelligence.—Official List of Changes in the Medical Corps of the United States Navy for the week ending January 26, 1895:

Norton, O. D., Passed Assistant Surgeon. Ordered to the Naval Laboratory and Department of Instruction, Brooklyn, N. Y.

Berrymill, T. A., Passed Assistant Surgeon. Detached from the Naval Laboratory and Department of Instruction and ordered to the Naval Hospital, Brooklyn, N. Y.

Hope, J. S., Assistant Surgeon. Ordered to examination preliminary to promotion. March 4, 1895.

Marine-Hospital Service.—Official List of the Changes of Stations and Duties of Medical Officers of the United States Marine-Hospital Service for the Sixteen Days ending January 31, 1895:

The Medical Society of the State of New York, in session in Albany this week, has unanimously elected Dr. Roswell Park, of Buffalo, president for the ensuing year.

Society Meetings for the Coming Week:

MONDAY, February 11th: New York Academy of Medicine (Section in General Surgery); New York Ophthalmological Society (private); New York Medical-historical Society (private—Anniversary); New York Academy of Sciences (Section in Chemistry and Technology); Lenox Medical and Surgical Society, New York (private); Boston Society for Medical Improvement; Gynecological Society of Boston; Maine Academy of Medicine (Portland); Burlington, Vt., Medical and Surgical Club; Norwalk, Conn., Medical Society (private).

TUESDAY, February 12th: New York Academy of Medicine (Section in Gastro-enteric Surgery); New York Medical Union (private); Kings County, N. Y., Medical Association; Medical Society of the County of Rensselaer, N. Y.; Newark, N. J. (private), and Trenton, N. J., Medical Associations; Clinical Society of the Elizabeth, N. J., General Hospital and Dispensary; Northwestern Medical Society of Philadelphia; Practitioners' Club, Richmond, Ky.

WEDNESDAY, February 13th: New York Surgical Society; New York Pathological Society; American Microsurgical Society of the City of New York; Metropolitan Medical Society, New York (private); Medical Societies of the Counties of Albany and Allegany (quarterly), N. Y.; Pittsfield, Mass., Medical Association (private); Franklin, Mass., Dis-
strict Medical Society (quarterly—Greenfield); Philadelphia County Medical Society.

THURSDAY, February 14th: New York Laryngological Society; Society of Medical Jurisprudence and State Medicine, New York; Brooklyn Pathological Society; Medical Society of the County of Cayuga, N. Y.; South Boston, Mass., Medical Club (private); Pathological Society of Philadelphia.

FRIDAY, February 15th: New York Academy of Medicine (Section in Orthopedic Surgery); Baltimore Clinical Society; Chicago Gynecological Society.

SATURDAY, February 16th: Clinical Society of the New York Post-graduate Medical School and Hospital.

Births, Marriages, and Deaths.

Died.

Strong.—In Cleveland, O., on Tuesday, January 29th, Dr. Jamin Strong, aged seventy years.

Letters to the Editor.

RAPID DILATATION OF THE CERVIX UTERI.

LAGRANGE, KY., January 17, 1895.

To the Editor of the New York Medical Journal:

Sir: I have just read Dr. Edgar's paper in your issue of the 12th inst., on Duchrisses's Method of Deep Cervical Incision for Rapid Delivery, and it recalled a case in my own practice which I thought might be of interest to your readers. A negress, a primipara, aged eighteen, was pregnant seven or eight months.

I found her in the most violent convulsions, the convulsions following each other so rapidly as to be almost continuous. I began to give chloroform, introduced my finger, and soon got one finger into the os. I sent for my obstetrical case, and by the time it reached me, which was after nearly an hour, I had succeeded in introducing two fingers. In the meantime the case had been growing worse and each seizure seemed as if it would be the last. I opened my case of instruments with no hope of finding anything I could use, but picked up a large placental forceps. I looked at it and opened the blades several times in my hands, and found them very powerful, and it occurred to me in my desperation that they would dilate any cavity, so I quickly introduced them into the os and by a slow, steady pressure of twenty or thirty seconds, with intervals of ten or fifteen seconds, in less than ten minutes I had succeeded in dilating sufficiently to introduce my large forceps, and delivered in about half an hour. There was an immediate gush of an enormous quantity of blood. I passed my hand into the uterus and tore away the placenta. Then, holding my hand in the uterus, I had my assistant saturate a ball of cotton with tincture of perchloride of iron, the only hemostatic I had, and introduced it. The uterus immediately contracted and all hemorrhage ceased. The child was stillborn and no effort was made to resuscitate it. The mother remained in a comatose condition for several hours, when consciousness returned and she made a good recovery. The only damage was a slight laceration of the perineum.

If you think this experience of a country doctor's, who must do what he can with what he may happen to have, will be of any benefit to your readers, I should be glad to have you use it.

John F. Taylor, M. D.

TABLES OF INTESTINAL OPERATIONS.

ROCHESTER, MINN., February 2, 1895.

To the Editor of the New York Medical Journal:

Sir: In the issue of your Journal for January 19, 1895, under the heading of Tables of Intestinal Operations, Dr. F. H. Wiggin writes a letter in which he states that a table of intestinal anastomosis used by us in an article printed in the January number of the Annals of Surgery is similar to the one read by him in October, 1894, and printed in your Journal in December, 1894, and implies that we have copied his table without due acknowledgment. In reply, we would say that the table in question was furnished us by Dr. J. H. Murphy, and that we so stated in our paper, from which we quote the following:

"Through the kindness of Dr. Murphy we append here with a tabulated statement," etc., and, further, that this table was sent to us by Dr. Murphy in September, and that our paper as printed, including the table, was in the hands of the editor of the Annals of Surgery in September (although not printed until January), one month before the paper of Dr. Wiggin was read, and more than two months before it was published.

W. J. Mayo, M. D.,
C. H. Mayo, M. D.

THE MORPHINE HABIT IN CHILDREN.

BROOKLYN, February 1, 1895.

To the Editor of the New York Medical Journal:

Sir: I am desirous of adding to the clinical literature of morphinism in children. If any reader of your journal has met with a case, and will furnish me full details, I shall appreciate the favor and give due credit.

J. B. Mattison, M. D.

Proceedings of Societies.

AMERICAN ASSOCIATION OF GENITO-URINARY SURGEONS.

Eighth Annual Meeting, held in Washington, May 29, 30 and 31, and June 1, 1894.

The President, Dr. George Cistmore, of San Francisco, in the Chair.

(Concluded from page 152.)

The Question of Surgical Interference in Tuberculous Kidney.—Dr. John P. Bryson, of St. Louis, read a paper on this subject. The author stated that of a hundred and seventy-four cases observed by him sufficiently to justify the positive diagnosis of tubercular disease of the urinie organs, only eighteen had given unmistakable evidences of involvement of the kidneys. This statement was, of course, intended to apply only to cases of surgical as distinguished from the more generalized tuberculosis known as miliary. Surgical interference in tuberculous disease of the kidneys had been recommended (1) to clear up the diagnosis and remove possible stone; (2) to free sloughing portions of the renal substance; (3) to drain the renal pelvis and avoid the infection of the lower urinary passages by diverting the stream of tuberculous urine by the blad; (4) splitting the capsule to avoid extensive sloughing in cases where the onset was sudden and large portions of the organ were threat-
ended; and (5) nephrectomy in cases where the kidney was sufficiently disorganized by strumous disease to be no longer useful as an excretory organ, and but threatened the general health.

The complexity of the problem of surgical tuberculosis, the fact that experiment was not an adequate substitute for experience, and the knowledge that here we were dealing with organs so essential to the maintenance of life, rendered it impossible to study these propositions otherwise than by trial; that was to say, by the light of what had actually been done clinically, and the results that had been thus obtained. The researches of Morris and others showed that in a little more than one half the cases examined, both kidneys had been diseased, though not to the same extent. This fact was sufficient to warn against any serious interference with the diseased organ, excepting in cases of urgent necessity. Not only might the second kidney be diseased, but it might be absent, or other tuberculous foci might exist elsewhere in the body, which, though latent, were ready to become active sources of infection at any moment. The author stated that merely draining a tuberculous cavity in any part of the body had not proved a satisfactory procedure in his hands, even where the drainage had been complete, or combined with washing and the application of antiseptics. If we might reason by analogy from similar conditions of the testis, splitting the capsule in those cases of sudden onset with rapid swelling, in order to prevent considerable destruction of gland tissues, was not so effective as rest, combined with emollient and antiseptic local applications. In one case of this kind coming under the author's observation, in which the capsule of the kidney had been split, the patient had died in a fortnight from general tuberculosis. Where the symptoms of stone were fairly clear, an operation for its removal seemed to be justifiable; but the danger of lighting a chronic into an acute renal tuberculosis was too great to justify an operation for the purpose of clearing up a doubtful diagnosis, when intelligent and patient watching would surely, in the great majority of cases, solve the problem. To remove a stone; to open an abscess that was not adequately draining by the ureter, and thus relieve fever and wasting suppuration; to free sloughing portions of the kidney, and thus prevent infection of the pelvis and circum-renal tissues, and, when we could satisfy ourselves reasonably well of the adequacy of the opposite kidney, to remove a kidney that was disorganized and causing wasting by suppuration, seemed to be plain surgical duties; but to remove or even to incise and drain any portion of a kidney with the object of removing a focus that was likely to infect the body was not, in the writer's opinion, a justifiable proceeding.

Dr. Bangs said that, after a good deal of experimentation in this class of cases, he had come to the conclusion that good hygiene was the chief if not the only factor in the cure of tuberculosis.

Dr. Keys expressed the opinion that in these cases the surgeon should either stand aside or else play the physician, and only operate when an emergency demanded it.

Dr. Belfield said that he thoroughly believed in non-interference in tuberculosis of the genital-urinary organs.

Dr. Bell said that in cases where the tubercular lesions were limited to the bladder and prostatic region he had had very satisfactory results from opening the bladder above the pubes, and then instilling prolonged drainage after cauterizing the diseased areas.

The President said that he had become very conservative as regarded the use of instruments in tuberculous patients.

A Case of Cystitis and Nephropathy due to the Colon Bacillus, requiring Nephrectomy.—Dr. F. Tilden Brown, of New York, reported a case of this affection. The patient had been a male, aged forty years, who in 1888 had been treated for cystitis. Upon leaving the hospital the symptoms of cystitis had been replaced by those of pyelitis or pylonephritis; in this condition he had remained for some years, during which time he had steadily grown worse. On his readmission to the hospital in January, 1894, there had been pain and resistance on palpation on the left side, and well up under the border of the ribs an indurated mass could be felt. In February, 1894, an operation had been undertaken, and on exposing the left kidney it had been found to consist of a large, thin-walled sacculated bag filled with fluid. Nephrectomy had accordingly been done, and the patient had made a good recovery. In the course of the operation the renal artery had been ruptured, producing alarming haemorrhage.

Cultures made from a sinus of the removed kidney had yielded a pure growth of colon bacilli. Cultures of the urine, drawn with a sterilized catheter six weeks after the operation, and again three months after the operation, had also yielded pure cultures of the same bacillus. In conclusion, the reader said that the title of this report was purposely made assertive as regarded its aetiology, rather with the intent to elicit discussion upon the importance or non-importance of the Bacillus coli communis as a pathogenie agent in urinary diseases, and because this particular case afforded unusual facilities for positive deductions.

Dr. R. W. Taylor exhibited a colored drawing showing a mixed malignant growth of the testis.

Dr. Bryson said that tumors in the region of the testis or cord were seldom typical; they were apt to be composed of mixed elements, and in the treatment of these cases radical measures were usually indicated.

Dr. Bangs said that in one case of carcinoma of the testis that had come under his observation the inguinal glands had not been removed, and two years later there had been a recurrence of the disease in the kidney on the affected side; the inguinal glands had not been involved.

Dr. Bryson said that in one case of sarcous of the testis there had been a recurrence of the disease in the intrabdominal glands. The inguinal glands had escaped.

Dr. Keys said that in a number of these mixed growths of the testis that he had seen the recurrence in each instance had been in the retroperitoneal glands.

Two Cases of Syphilis bearing on the Question of the Period during which the Disease is Communicable.—Dr. James Bell, of Montreal, reported two such cases: 1. A case of transmission of syphilis from the male two years after the disappearance of all lesions. The patient had presented himself some years ago with a well-marked and characteristic primary sore, followed by typical skin, glandular, and throat symptoms. He had at once been placed on specific treatment, and this had been faithfully continued for over two years, at which time the man had had no further evidences of the disease. Two years and eight months after the disappearance of the initial lesion the man had been married, and about two months later his wife, who had been in every respect above suspicion, had had unmistakable symptoms of syphilis. The reader said he regarded this case as one of blood inoculation.

2. Conception occurring during the period of incubation of the chancre in the male parent; the product being a perfectly healthy non-syphilitic child. The patient had been a man who had exposed himself to inoculation in the latter part of October, 1891. Four days afterward he had been married. In January, 1892, he had presented himself with a large, indurated chancre and fully developed secondary symptoms. His wife had ceased to menstruate a week before marriage, and had not menstruated since. She had shown other signs of pregnancy and her child had been born about the middle of August, 1892. Conception must therefore have occurred during the interval.
PROCEEDINGS OF SOCIETIES.

which had elapsed between the inoculation and the appearance of the chancre. The woman had been at once made aware of the grave condition of affairs by her husband and had been put on specific treatment. She had remained in good health, and had been delivered at full term of a fine, healthy child. Up to the present time neither the mother nor the child had shown any signs of syphilis.

Dr. Taylor said that in the first case reported there had possibly been some extra- genital source of infection. The woman might have been infected by some other member of the family. In one case that he had heard of a servant had been the source of infection; in another, a child. Or the infectious period of the disease might have persisted for an unusually long time. The blood was the least potent agent in the infection of syphilis. The second case reported Dr. Taylor said he regarded simply as fortuitous.

Dr. Jenkins referred to a case in which a man had married four months after the appearance of the initial lesion. Two months later his wife had shown unmistakable symptoms of syphilis, and since then she had aborted five times.

Dr. Keys said that in the case reported the man had married twenty-eight months after the appearance of the chancre. Clearly he had not yet been out of the high-road of possible infection, no matter what the treatment had been.

Dr. Bangs said he had arrived at the conclusion that it was not safe to permit marriage in these cases until after three years had elapsed.

Officers for the Ensuing Year were elected as follows: President, Dr. L. Bolton Bangs, of New York; vice president, Dr. Francis S. Watson, of Boston; secretary and treasurer, Dr. W. K. Otis, of New York; member of the council at large, Dr. J. A. Fordyce, of New York. It was decided to hold the next meeting at the Clifton House, Niagara Falls, during the last week in May, 1895.

COLLEGE OF PHYSICIANS OF PHILADELPHIA.

SECTION IN GENERAL SURGERY.

Meeting of November 9, 1894.

Dr. John B. Roberts in the Chair.

(Concluded from page 53.)

The Antitoxine Treatment of Diphtheria.—Dr. George A. Munkleck read a paper on this subject in which he said that the employment of pure cultures of pathogenic micro-organisms and their toxic products for purposes of conferring immunity, as well as for combating certain infectious diseases, was comparatively of recent date. The history of the labors of Pasteur, Koch, Kitasato, and others in this field had become common property for the entire medical world, so that a mention of them here would be superfluous; but their work had opened up new avenues of investigation and research which had already yielded practical results, as it seemed, of the most far-reaching consequence, and a promise of still greater achievements in the future. The speaker referred here especially to the work of Behring, Ehrlich, Brüger, Wernicke, Boer, Schneitz, Kitasato, Wassermann, Kossel, Auroson, and others in Germany, and to that of Roux and Yersin in France, and Tizzoni in Italy, as a result of which the doctrine of conferring immunity against certain infectious diseases had been further elucidated and experimentally confirmed on animals at least. Behring and his co-laborer had been the first to show that the blood or milk of animals so treated had the power, when injected hypodermically, or into the peritoneal cavity, to confer immunity upon other animals or to protect them from the consequences of inoculation of virulent cultures of pathogenic micro-organisms, or intoxication by the products of the same species with which the first animal had been made refractory. In other words, the milk and blood-serum had been endowed with antitoxic properties which had the power to neutralize the toxic action of the virulent cultures and their products. This neutralization of the toxic by the antitoxic principle took place even outside of the animal economy when they were mixed in a test-tube in obedience to the laws of proportion. Animals which had been made ill by the injection of fatal doses of virulent cultures of their filtrates were restored to health if a sufficient quantity of antitoxic serum was injected within a stated time. Of the infectious diseases which had been the subjects of this line of investigation, and in which the results had been most encouraging, tetanus and diphtheria, and, to some extent, streptococcosis infection, were pre-eminently to be mentioned. Of these, however, only diphtheria was relevant to this paper; the principles involved were, however, the same in all. Behring's method of securing the antitoxic serum of diphtheria for therapeutic purposes was similar to that now generally accepted by all investigators—by injecting hypodermically into an animal gradually increased doses of attenuated dead cultures of the Klebs-Löffler bacillus in order to effect a certain degree of basal immunity. Subsequently this basal immunity was intensified by injecting increased quantities of living and virulent cultures.

This method was based upon the fact already established by the investigations of Koch and Kitasato, that specific toxine and antitoxine neutralized each other immediately outside of the living organism when mixed in the test-tube in obedience to the law of proportion. Formerly toxine and antitoxine had been injected separately, but owing to variations for absorption exact results could not be obtained. Now they were injected together. For the practical application of the method it was best to use a test toxine the immunity-conferring power of which had been tested, and which was derived from a mature bovine culture to which had been added 0.5 per cent. of phenol. Of the solution used by Behring and his collaborators as a test poison, 0.3 c. c. represented the minimal fatal dose of 1,000 grammes body-weight; 0.8 c. c. of this solution was injected into an animal weighing 200 to 300 grammes, together with the substances to be tested for the antitoxic power in decreasing proportions.

For example, 0.4 c. c., 0.3 c. c., 0.2 c. c., etc. The result could be determined approximately in twenty-four hours, and with accuracy in forty-eight hours, by the presence or absence of local oedema, provided the proportions of the material to be treated for its antitoxic power had been properly measured. The quantity necessary to neutralize 0.8 of this test toxine would vary according to the amount of antitoxine present. These injections were made serially, and always gave absolutely reliable results. As a final result of their labors these investigators had animals of whose serum a milligramme and a half, or of whose milk 0.075 milligramme, were sufficient to neutralize 0.8 c. c. of this normal toxine solution. A serum was said by Behring to represent 1 antitoxine normal if 1.0 c. c. to 100 body-weight was sufficient to neutralize 0.8 c. c. of this normal toxine solution—that is, if 0.8 c. c. of this toxic solution was injected into a medium-sized guinea-pig (about 500) it would remain well if normal antitoxin serum in the proportion of 1 to 100 body-weight (about 5 e. c.) had been injected a quarter of an hour previously. In this manner serum had been obtained representing sixty and more antitoxine normals.

Roux, who had begun his experiments in 1891, used for purposes of immunity a test poison 0.1 c. c. of which would kill a guinea-pig of 500 grammes in from twenty-four to forty-eight hours. His test poison was attenuated with a solution of iodine. He gradually increased the dose by diminishing the
proportion of iodine. After several weeks it was given pure. In this very powerful antitoxic serum, with a power of immunity of 1: 50,000, was obtained.

Since the beginning of the year 1894 antitoxic serum had been extensively used in cases of diphtheria in the hospitals of Berlin and Paris. Henoch, Heunner, Koch, Kosset, and others testified to its absolute harmlessness even in doses of 90 c.c. In no instance had any irritation of the kidneys or any unfavorable influence on the general health been observed. In six Berlin hospitals 220 cases had been treated, with 76.4 per cent. of recoveries. Among these had been 67 tracheotomies, with 57 recoveries—51.1 per cent. The beneficial effect of the treatment had been most apparent the earlier it had been begun. Of six treated on the first day, all had recovered; of 66 treated on the second day, 61 had recovered—97 per cent.; of 29 treated on the third day, 25 had recovered—86 per cent.; of 29 treated on the fourth day, 30 had recovered—77 per cent.; and of 23 treated on the fifth day, 13 had recovered—56 per cent.

Roux, of Paris, reported a mortality of 24 per cent. in the Materiné, while the mortality in the Tronseau Hospital, where no serum had been used, had been 69 per cent. during the same epidemic.

Dr. Muehleck then reported four cases treated by this method, and said that he presented them for the consideration of his colleagues, being well aware that their number was too small to permit of any definite conclusion as to the value of the serum-therapy of diphtheria, all the cases, moreover, having been treated, in addition to the serum-therapy, according to the generally accepted rules of practice. Nevertheless, the cases here presented had shown some features so striking that they had appeared to be of interest. After each injection a rapid fall of temperature had been noted, as would be seen. This reduction, however, lasted only twenty-four hours, but when it rose again, it never reached its original degree. In Case I, where two injections had been made, the same phenomena had been observed after each. At the same time a marked amelioration in the difficulty of breathing had been noted. The heart had been much less favorably influenced, being often irregular and weak. Nevertheless, he felt that if a sufficient quantity of serum had been at his disposal, and repeated injections could have been made, the toxine still remaining in the circulation might have been more effectually neutralized and its depressing effects on the heart avoided. The behavior of the membranes had been peculiar, inasmuch as they had not seemed to thrive; they had failed to spread, and in from twenty-four to forty-eight hours after the injection they had assumed a fatty, palpable appearance, and in each instance had disappeared within a week. The cases as a whole had run a milder course. The speaker did not think that the cases could be called mild ones, since the two children who had not been treated with antitoxine serum had died. The continued presence of probably virulent Klebs-Löffler bacilli in the throats of two of the other children, who, he thought, indicate that antitoxine serum did not kill the micro-organisms themselves, but merely neutralized their poisonous products, and that consequently isolation and proper disinfection of the throat were indicated as heretofore.

Dr. H. A. Hare said he had had the honor of being invited to be present at the Municipal Hospital when the inoculations had been made by Dr. Fischer, of New York, but thought he could add very little to Dr. Muehleck's report. There were, however, several things which had impressed him very forcibly at the time of making these experiments, which he had not had time to clear up. One was that the cases had been desperate ones, fairly rotten with sepsis; one could scarcely believe it possible that children could survive such profound poisoning. Some of them had been simply gasping for air, not from ob-

struction, but from prostration of the vital powers. Some had had as much as sixty per cent. of albumin in the urine, the pulse had been indistinct and scarcely to be found at the wrist; while the most careful auscultation had been needed to distinguish the heart sounds. The membranes had spread from the throat to the lips and the nose. Such patients had been among those that had received the injections. What the result was it was too soon to say, but he had been impressed with the thought that the test in these cases could only end in failure. If the treatment could be given at an early stage, before the kidneys, the heart, and other important organs had become so seriously involved, it might be useful. Dr. Fischer had thought the cases desperate, but declared that the severe cases had been the most favorable for the test. In one case he had used an Aronson's solution, which was three times as strong as Behring's. The speaker believed that one of the patients who had received the antitoxine was still alive and in about the same condition; the others he had not heard from.

Now, if, as everybody believed, diphtheria was primarily a local disease, caused by infection with the bacilli whose growth caused the development of toxine, he confessed that he would rather take his chances with the toxine than to inject any amount of the immunizing serum into his blood. The child had had to struggle not only against the toxine of the Klebs-Löffler bacillus, but also against the toxines of the other bacilli, which caused so-called pseudo-diphtheria, and the ordinary bacteria of inflammation and suppuration, and the use of antitoxine might, for all we knew, increase the strain on the organism.

Dr. C. A. Frese gave his experience with the antitoxine. It had first been tried upon a patient of Dr. Woodward's, in a family where three had been attacked by diphtheria. The child had been in a desperate condition and had died three hours after the injection. Cultures had been made and the Klebs-Löffler bacillus had been found; also staphylococci and streptococci. The third child had just begun to get sick, and nothing had been seen of false membrane in the throat.

In that case the child had been exposed to the infection. One tenth of a bottle of the antitoxine had been used, and the patient had recovered from her malaise without any membrane forming. Two other cases were cited by Dr. Frese in which the antitoxine had been used with good results.

Dr. Edwin Rosenthal said that it had been with peculiar care that he had followed Dr. Muehleck's experiments with their satisfactory results. In the statistics presented on the treatment of diphtheria by antitoxine, the greatest proportion of recoveries had been shown in cases where the treatment had been begun on the first day of the disease. These statistics had been classified peculiarly, and had reference to the number of days during which the patients had been ill before the treatment had been begun. They had no reference to the gravity of the disease or to the complications. As such, their value must, in some way, be diminished, for we all knew that cases of diphtheria seen early enough could be so treated that the infection became modified, and recovery was the rule. For this reason the old method of treatment might be classed as equally good; and many a physician, notably Dr. A. Klein, who had seen many cases of diphtheria, had a record of no deaths. He believed that, in those desperate cases—a case as described by Dr. Hare—the real efficacy of antitoxine could be tested. But, nevertheless, the cases reported by Dr. Muehleck had proved that its use prevented the full development of the disease, and if developed, decreased the gravity of the symptoms to a remarkable extent.

In the statistics of the cases in which tracheotomy had been performed, he could not see anything remarkable, as he
thought Dr. Wharton's statistics of the present plan of treatment equally good; however, if, with one or more injections of antitoxine, the course of such cases could be shortened, we had assuredly a good remedy. In Dr. Muehleck's paper no mention had been made of patients with laryngeal diphtheria intubated and treated by antitoxine. All the statistics he had seen on this special subject had recorded no deaths; a record which certainly placed antitoxine foremost as a remedy. The first case in which Dr. Muehleck had used the injections had been one of laryngeal diphtheria, and the speaker had been present when he had made his first injection, using Aronson's serum, manufactured by Schering. Though the stenosis had been marked, intubation had not been practiced, and on the second night, when suffocation had appeared imminent, Dr. Muehleck, at the suggestion of Dr. Klein, had postponed intubation, but had given a second injection; and this patient had recovered. This recovery had been deemed by Dr. Muehleck to be due to the employment of the remedy, for no other special means had been employed; surely another demonstration proving its efficacy.

Dr. A. Klein said that the cases referred to by Dr. Rosenthal had been mostly mild ones, and the patients would have recovered under any ordinary treatment. The cases he had seen with Dr. Muehleck had been of a different type entirely. In the first one, stenosis had been so marked that intubation or tracheotomy had been considered, but in order to give the antitoxin a fair trial it had been decided to give a second injection and to wait for surgical interference until the symptoms grew more urgent. The patient, as reported, had recovered.

In addition to the statistics referred to, which were in favor of antitoxine, the speaker mentioned thirty-five patients who had been treated by Dr. Bokai in Budapest with antitoxin exclusively, nineteen of whom had had the severest type, sixteen having had to be intubated. Of the thirty-five patients eight had died; all the intubated ones had recovered.

Dr. D. Beaden Kyle said that he could add nothing to the observations already cited as to the clinical effects of antitoxine, but he might add something in regard to the examination of cases for the bacilli. What had been said in regard to the presence of other organisms was quite true. In all the cases he had studied, where streptococci had been present, the disease had been more malignant than if the staphylococci had been present; as a rule, many germs were present besides the Klebs-Löffler bacilli. The germ of false diphtheria (von Hoffmann's) was so much like the germ of true diphtheria that it might be necessary to resort to the inoculation of animals to make the diagnosis. If inoculations were made on blood-serum and inoculated, the first growth to appear on the surface of the serum was, as a rule, the Klebs-Löffler bacillus, and in most cases the diagnosis could be based on stains from these growths; only in the older cultures was there any marked difference.

Aronson's serum was of several degrees of strength; one of the preparations, labeled diphtheria antitoxin, was not intended for the treatment of diphtheria, but for the purpose of securing immunity. Dr. Kyle exhibited a number of microscopic slides showing the germs from tubes eighteen hours after inoculation, and also from an older growth, from which the marked variance in form could be observed.

Dr. T. Xaïné remarked that, with regard to the so-called pseudo-bacillus, some German pathologists denied that there was any difference. Some French authorities, on the other hand, affirmed that there was a distinction; that the pseudo-bacillus was shorter and grew more rapidly in culture media. It was also asserted that it might be found in the throat during perfect health, also in the throats of individuals living in communities where there never had been diphtheria. It was said that the pseudo-bacillus was found in fifteen or twenty per cent. of healthy children, and that the virulent bacillus might lose its virulence; but by culture in suitable media this might be restored. The speaker had injected into the trachea of a rabbit 1 c. c. of a solution of the Klebs-Löffler bacillus bouillon culture. The rabbit had then had symptoms of dyspnea. He had had a beautiful membrane throughout the larynx down to the bifurcation of the trachea. On examining cultures of the bacilli, Dr. Xaïné had found that they had regained their virulence and former thickness. He thought that in New York physicians did not recognize any distinction between the true and false diphteritic bacillus, and considered them all as diphtheria germs. He thought that Dr. Abbott also did not believe that there was any difference between the true and false diphteritic bacillus. As regarded streptococci and staphylococci, they were always found in the mouth, and their presence only indicated a double infection.

Dr. Muehleck thought that every experienced physician would agree with him that there were very few chapters in medicine more disappointing than that on the treatment of diphtheria. In fact, the treatment until now had amounted to very little; it being always a question in his mind whether the patient had not been more injured than benefited by the attempt to make applications of disinfecting solutions to the throat in the case of a struggling child with a weak heart. The results from surgery had been even more desperate. Anything, therefore, that would afford a ray of hope should be welcomed with delight. The cases he had seen were too few for a conclusive opinion, but the results from Europe were very favorable. Virchow, who was usually very conservative in such matters, had indorsed this treatment. The prognosis depended largely upon the day of the disease when the treatment was begun, as he had already said in his paper. Behring and Prudden had shown that sepsis by streptococci invasion was common in the later stage of the disease. The former distinctly stated that the antitoxine was powerless against such infection.
presence of a combustible gas in the blood or of a trace of carbon dioxide in confined air.

In the second part he explains the law of the absorption of carbon dioxide that he has discovered, and indicates some interesting applications of this law to the hygiene of heating and ventilation. He then gives some data regarding the determination of fire-damp in mines.

The author has endeavored to make this a plain, concise, and practical work that will appeal to persons of only a general education. Brief directions for the use of disinfectants, the care of the patient, the conduct of the nurse, and the detail of the sick-room and the house are given; then follow sections on disinfection in various communicable diseases. The author has not aimed to tell anything new, but rather to present what is known in a form in which it may be turned to practical account readily.

The author's experience as assistant superintendent to two nurses' training schools has undoubtedly proved of value to her in indicating what a nurse should be taught in the important subjects of anatomy and physiology.

This volume is arranged in twenty chapters that comprise thirty-seven lessons, and seems to include such information as will be useful to the nurse in fulfilling her duties.

REPORTS ON THE PROGRESS OF MEDICINE.

Physiological Chemistry.

By Ernest Ellsworth Smith, Ph. D.

The Influence of Alum, etc., on Digestion.—It is generally believed that aluminum compounds, which have been used extensively in the adulteration of flour and in baking powders, both impede digestion and have an injurious effect on the digestive organs. In a recent series of experiments by Bigelow and Hamilton (Jour. of the Amer. Chem. Soc., 1894) the influence of these compounds was studied, not only upon the digestive action of pepsin and hydrochloric acid, but also upon artificial digestion in pancreatic juice. Alum interfered materially with the action of the gastric juice, but the pancreatic juice affected the digestion of the remaining portion of food, which should have been digested by the pepsin. The same was true of the digestion of matters containing aluminum hydroxide. The action of aluminum phosphate was quite different, however, for notwithstanding the supposed insolubility of this compound, ten or twelve per cent. of the albuminous which were digestible in the presence of alum or aluminum hydroxide appeared to be insoluble in the presence of an equivalent amount of the phosphate.

The Chemical Pathology of Uremia.—In a recent experimental study of uremia, Hughes and Carter have contributed to the pathology of this important condition (Amcr. Journ. of the Med. Sciences). They conclude that there is one poison, present alike in uric acid, human blood, in lipoprotein effusions in uremia, and in dog's blood in experimental uremia; and that this poison is not one of the ordinarily recognized constituents of the urine, as generally believed, but one whose nature or even existence has not before been recognized. The facts that its action is much lessened after subjection to moderate heat, and that it is not readily dialyzable, seem to indicate that the poison is an albuminous body; while clinical evidence indicates that it is not a constant constituent of the blood, but produces the uremic condition by accumulation, owing to the inability of the kidneys to excrete it, or more rarely by a sudden and enormous production. The order in which renal sickness stand as to their toxicity, proceeding from the most toxic to the least, is, man's, the dog's, the horse's. This suggests to the writers that the origin of the substance is to be traced to the character of the food, which is more nearly carnivorous with man and the dog and purely herbivorous with the horse, and that its production takes place somewhere in the digestive tract.

The Influence of Massage on Metabolism.—Bendix has found (Zeit. f. klin. Med., xxv) an increase in both the volume of urine passed during periods of massage treatment and the absolute amount of nitrogen excreted. The periods extended through several days to a week and the results obtained were compared with fore and after periods of equal duration, during all of which the subject was in nitrogenous equilibrium. There was a diminished separation of fat in the faces during the massage period, indicating better absorption from the alimentary tract.

Lactic Acid in the Stomach.—J. Boas has recently applied a new method of estimating the presence and quantity of lactic acid (Munchener med. Wochenschrift, 1893, No. 43) to the study of the gastric contents of normal and diseased individuals at varying intervals after the ingestion of the test meal (Zeit. f. klin. Med., xix), and finds that notwithstanding stagnation from motor insufficiency and diminished hydrochloric-acid production, lactic-acid formation does not occur except in the presence of a third factor which is generally supplied in cases of carcinoma of the stomach. When positive, therefore, he considers the test of diagnostic value in doubtful cases of this kind, but not contraindicative when negative.

Respiratory Products in Diabetics Mellitus.—Weintraub and Laves have studied (Zeit. f. physiol. Chem., xix) the inspired and expired air of diabetics with the aid of an apparatus after the principle of Regnault, devised by F. Hoppe-Seyler. The patients had been kept for a month on restricted diet (protein and fat) in metabolic and nitrogenous equilibrium, and the urine was free, or nearly free, from sugar. The absolute amount of oxygen taken up was as much as in health. A lower value for the respiratory quotient was found, which is explained by assuming the oxidation of carbon-containing substances not in the food, presumably glycogen, and also the formation of acetone, acetoacetic and oxbutyric acids from higher fatty acids. The addition of carbohydrate food produced a slight increase in the carbon dioxide and raised the respiratory quotient a little, showing the diminished ability of the system in these cases to oxidize sugar.

Carbohydrate Metabolism in a Diabetic Dog.—Clinical experience has demonstrated the advantage of levo-rotary over dextro-rotary carbohydrates in the diet of diabetic patients. Weintraub and Laves, working on a dog with diabetic following removal of the pancreas (Zeit. f. physiol. Chem., xix), have sought to determine the fate of the carbohydrates; whether in each case they are stored away as glycogen or give rise to increased carbohydrate combustion, in this latter instance increasing the amount of carbon dioxide expired and raising the respiratory quotient. The results show in the case of the levo-rotary a higher respiratory quotient, indicating an increased combustion, while with dextro-rotary sugars the respiratory quotient remained constant.

A Carbohydrate in Normal Urine.—Baisch finds (Zeit. f. physiol. Chem., xix) in two liters, representing twenty-four hours' urine, an average of 0.12 gramme dextrose and 0.19 gramme of reducing non-fermenting carbohydrate.

The Estimation of Cystin in Urine.—Borisow (Zeit. f. physiol. Chem., xix) gives the following method: Five hundred cubic centimetres of urine are treated on the water bath with twenty cubic centimetres of dilute hydrochloric acid and zinc. To the filtrate are added ten grammes mercuric chloride and ten grammes of sodium acetate in concentrated solutions. After the
removal of the mercury from the new filtrate with hydrogen sulphide and the removal of this with carbon dioxide, the solution is concentrated and again treated with hydrochloric acid and zinc and mercuric chloride and sodium acetate as before, which precipitate all the cystin. The united mercury precipitates are suspended in water and decomposed with hydrogen sulphide, the excess of this gas removed from the filtrate by carbon dioxide, and the solution then evaporated to dryness on the water bath. The residue is twice extracted with absolute alcohol and then dissolved in a little ammonium, which is filtered and mixed with ten volumes of alcohol. The solution is separated from the precipitate formed, and the latter is dissolved in ammonia and again precipitated with alcohol as before. The united filtrates are evaporated and the residue is dissolved in ammonia and precipitated with alcohol. The precipitates obtained are cystin, together with considerable foreign substances. The actual amount of cystin is calculated from the amount of sulphur, which is estimated by the method of Carius. In the case studied the amount was 0.05 per cent., or about a gramme in twenty-four hours. Diamines were found present in large amounts in the feces.

The Fat of Women's Milk.—Laves finds (Zeit. f. physiol. Chem., xix) that the fat of women's milk is very poor in volatile acids and those soluble in water, but contains a large amount of acids belonging to the unsaturated series. The volatile portion is composed largely of caproic, caprylic, and caprinic acids; the non-volatile, insoluble portion, of palmitic, stearic, and oleic acids, besides which are one or two acids of a lower molecular weight, including, perhaps, myristic acid. The melting point of the fatty acids is 37° to 39° C.; the melting point of the fat itself, 30° to 31° C. The chemical composition is thus quite different from that of cow's milk.

Proteids.—Many attempts have been made to express an empirical molecular formula for proteids, but little light has thus been obtained regarding their true structure; and the same is true of the several theories of their structure that have been successively proposed. While they have the advantage of being suggestive, they carry little proof. The only way open to obtain any real knowledge on this subject seems to be by the study of their decomposition products, and of these there are two classes, according to the way they are formed: 1. The cleavage products, still partaking of the proteid nature and but little removed from the original substance. 2. The crystalline products produced by more destructive decomposition. These latter exist in the gummy residue, and when the known products are separated, the chemist is accustomed to classify the remaining substances as unknown extractives. Recent years have seen an advance of our knowledge regarding both these classes of decomposition products.

The primary cleavage products are formed by ferment action in both peptic and pancreatic digestion, as well as by several vegetable ferment, and also by the action of hot water, superheated steam, and boiling acids. The proteid appears to yield two parts, well known as the hemi-moiety and anti-moiety of the proteid molecule. These differ in that, while the former is capable of yielding both leucine and tyrosin and other crystalline products, even by tryptic (pancreatic) digestion, the anti group of cleavage products yields no tyrosin, even by decomposing with dilute acids; and it does not give Millon's reaction, which is dependent upon the tyrosin residue of the proteid molecule. This, then, is the beginning of knowledge regarding the cleavage of albuminous substances, the formation of these two groups of products. Looking at the products from a different point of view, we have Kühne and Chittenden's classification of albumoses, or, more correctly, proteoses and peptones, these latter further removed from the original proteid and always formed through the stage of proteose. Looking at the products from this standpoint, the process is one of simple hydration with cleavage, since the successive products contain a diminishing amount of carbon.

The crystalline products of proteid decomposition are formed in part by pancreatic digestion, also by the action of acids and by the action of alkalies. But acids and bases do not act in the same way upon proteid matter. Both, in common, yield ammonia and amino-acids; but baryta, for example, yields oxalic and acetic acids, which decomposition by acids does not. In the decomposition of casein with hydrochloric acid and zinc chloride, Hlasiwetz and Habermann, investigators of twenty years ago, were able to separate leneice, tyrosin, aspartic acid, glutamic acid, and ammonia, yet there remained a viscid mother liquor from which they were unable to separate any crystalline products. Horbaezewski, in his study of this class of crystalline products, was likewise unable to separate anything further. Dreeschel, however, by the aid of more modern methods has recently been more successful. He, first using phosphorwolframic acid, and later by a method involving the formation of a silver-nitrate compound, was able to isolate two bases which he has called lysin or lysatin and lysatine. These bear much the same relation to one another as creatine and creatinine do. Lysine is, in fact, empirically homologous with creatine and also with ornithine, a base separating from the organism of birds as a conjugate compound, in place of hippuric acid in man, when benzoic acid is administered.

From the mother liquor a base bearing the formula C,H,N,O, has been separated, which with alcohol and hydrochloric acid at 140° breaks up into benzoic ethylester and the hydrochloride of diaminio-acetic acid. Phosphorwolframic acid has likewise separated from the mother liquor two bodies, C,H,N,O, and C,H,N,O.

Schützenberger, starting from our knowledge of these decomposition products, has attempted to form peptone and proteid matter synthetically, and has succeeded, by heating mixtures of amino compounds with urea and treating at a high temperature with phosphoric anhydride, in forming what he calls pseudo-peptone, which certainly does resemble peptone in its general reactions. It gives both the bluer and xanthoprotein reactions and is precipitable by tannin and picric acid and many salts and other compounds which react in a similar way with natural peptone. He has devised formulas and reactions to represent the synthetical formation of peptones, but they are far too theoretical and complicated to merit consideration here. This will suffice, however, to show that a steady and substantial progress is being made in the solution of these problems which constitute the necessary steps to the discovery of the chemical reactions which constitute life itself.
other in order to give the operator the necessary amount of room to operate. The changing of the position of the speculum or gag always occupies precious time, which, as we all know, is something we must overcome if possible. Operating in the mouth and giving ether at the same time is more or less difficult, and the fewer obstacles we have in the way the better. In casting about in my mind for an instrument that would hold the mouth open in a certain position and constructed in such a manner that it would practically be out of the way, allowing the operator to work without interference, I resorted to several methods, and had a few instruments constructed and tried them, but without any advantage.

At last I hit upon the idea of an instrument such as is shown in the accompanying cut, which I find answers every purpose.

The speculum is composed entirely of metal and rubber, the rubber being used to cover the plates on which the teeth rest, in order that they may not become broken or injured in any way. This speculum is about six inches long from tip to tip, and can be opened as wide as the mouth will permit.

\[ a \quad a \] are the plates on which the jaws rest. The rubber can be removed and renewed within a few minutes as often as desired.

The plates \( a \) can be moved to the rods \( b \) or be brought together. The speculum can therefore be applied to the mouth of any patient by spreading the hooks for adults or sliding them together for children. In case of a gap between the teeth the hook is passed upon the next sound tooth. The hooks or plates being turned up in front, elevate the lips and prevent their closing, thus admitting of a perfect view. The jaws can be opened or closed without removing the speculum by simply pressing the rods \( b \), which are held in place by the springs \( c \). The speculum can be easily cleaned or boiled without doing any harm or injury to any part, which is a great advantage over any wooden gag. Another great advantage is the small amount of space it takes up, and, being light, it can be carried in a very small space.

The instrument is manufactured by Messrs. George Tiemann & Co., of New York city, and is a model of neatness.

140 West Eight Street.

**Misellany.**

Is Strychnine an Antidote to Cobra Poison?—In the October number of the Transactions of the South Indian Branch of the British Medical Association there is a report of a paper on this subject which was read by Surgeon-Lieutenant H. H. Elliot, of Madras, who said that it had been his object to ascertain the value of strychnine as an antidote to snake poison, and the two courses which seemed to him to be open had been to experiment on the lower animals and on man. It must be remembered, he says, that the action is based on theoretical grounds so far as Indian snakes are concerned, that strychnine is a dangerous drug, and that it is often very difficult to determine whether any case is one of pathomorphological bite or not. Bearing such important considerations in mind, we can not, he thinks, refuse to accept the term experiment for the strychnine treatment of man.

Before describing his own methods the author cites two objections that have been put forward in regard to previous experiments on animals: 1. That they were carried out on dogs, and that one can not argue directly from one class of vertebrates to another, even though both are mammals. 2. That between the nervous system of man and that of the lower animals there is "only a functional analogy which has been mistaken for a complete identity." The first objection, says Dr. Elliot, occurred to him at the outset of his work, and he therefore did not limit himself to certain sets of vertebrate animals, but chose animals which would as much as possible represent the vertebrate kingdom, and especially the Mammalia. With regard to the second objection, he says, no one will contend that there is absolute identity between the nervous systems of two animals even of the same species, whether they are man or beast, but he strongly maintains not only that there is a functional analogy, but that there is an anatomical analogy, a physiological analogy, a pathological analogy, a clinical analogy, a therapeutical analogy, and in fact every kind of analogy between the nervous systems of man and those of the lower animals. It may reasonably be asked what evidence there is of this universal analogy between man and the lower animals in their reactions to cobra poison and strychnine, and in order to answer this the effects of these poisons on the animals which have been experimented upon must be compared with the well-known effects of the same agents on man; they will be found to be practically the same.

The strychnine check experiments will show that the first symptoms of strychnine treatment is a general bracing up of the nervous system; a few moments later the animal becomes alarmed and its movements tend to be spasmodic; it seems unable to stand comfortably, and a convulsion, either opisthotonic or emprosthrotic, throws it down. Clonic and tonic convulsions alternate, and respiratory spasms is severe, the embarrassment of the respiratory center being shown in the general lability and in the very rapid breathing during the intervals between the spasms. The least sound or touch brings on a fit in the animal, which left alone might lie still. The convulsions are attended with severe pain, and the patient usually dies in respiratory spasm or, more rarely, exhausted by frequent spasms. If death is averted, the animal recovers rapidly, the convulsive stage passing into a sleepy condition in which the nervous system seems to be profoundly exhausted, but in which condition the author has never seen an animal die.

With regard to cobra poison, in frogs and lizards the only noticeable points were that the animals showed signs of malaise, paralysis is rapidly supervened, spasmus usually occurs, and life was extinguished. The earliest symptoms noticed in the Mammalia were drowsiness and loss of control over the limbs, especially the hind limbs. After a short interval the sitting posture is given up, and soon the patient lies helpless, paralysed, and dying. The respiration toward the end is slow but not labored. The head is often ushered in by a little shudder, a clonic spasm of the limbs, in no wise comparable to the strychnine convolution. The cobra-poisoned animal retains its consciousness almost to the last. Salivation, says Dr. Elliot, was a very common feature of the case in the mammals experimented on. In dogs, pigs, goats, and monkeys, as well as in birds, it was a
practically unvarying symptom. An examination of the subcutaneous tissue at the seat of the injection showed an extravasation, evidently of an inflammatory nature, around the lesion. In monkeys two additional symptoms were present to which the author especially directs attention. The earliest sign of cobra poison in these animals was the dropping of the upper eyelids. This became so marked in time that the animals tilted their heads back and rolled their eyes down in order to see. This dropping was evidently paralytic. The other symptom was a condition frequently referred to in the notes on monkeys as drunkenness. The animals lost their power of co-ordination and staggered about with an extremely drunken look. In one case the monkey seemed to suffer from the optical delusion that a rope was in front of it.

Dr. Elliot alludes to Wall's description of a human being suffering from the results of a snake bite. Most striking, he says, are Wall's allusions to the early drooping of the eyelids and to the feeling of drunkenness, an account of which will be found in Wall's Indian Snake Poison. These and other points, he thinks, will establish that there is a very close analogy between the various Manararia, including man, in their behavior to the two poisons. Dr. Elliot describes a number of antidotal experiments made with strychnine in cases of cobra poisoning, and says that out of the whole number, thirty-three, he had not one single case of recovery to record; that in no case did the strychnine save life. Much, he says, must be allowed for the individual idiosyncrasies of animals, nevertheless he thinks that a lesson may be learned—namely, that, given an animal with a poisonous dose of cobra poison, the subcutaneous injection of strychnine often hastens death very noticeably, while it can not be said to retard it materially. It would seem, he says, that death may be hastened by the antidote in two ways: 1. By its increasing the force and speed of the circulation, thus aiding the diffusion of the virus. 2. By the exhausting reaction which strychnine undoubtedly produces on the nervous centers. The author adds that he believes that the supposed antidotal action of strychnine in cobra poisoning is a delusion and a myth. On comparing the strychnine check experiments with the antidotal experiments, he says, the following facts will be observed: 1. That symptoms of strychnine poisoning manifest themselves to said earlier after the injection of strychnine in the one case as in the other. 2. That in the early stages the convulsions of strychnine are as violent in the one case as in the other. 3. That in the later stages animals die from cobra poison with typical symptoms, and yet the least touch evokes an undoubted strychnine tremor in the animal up to within a minute of death. An intermediate stage occurs in which the victim starts on the least touch or sound, but does not respond with a convulsion. 4. That under the influence of a poisonous dose of strychnine the animal dies as surely when fully under the influence of cobra poison as it does when no such poison has been given. 5. That in some cases strychnine administered in physiological doses seemed actually to determine at once the impending fatal issue. 6. That in an animal poisoned with cobra virus strychnine may produce a temporary stimulation, and so may give rise to a hallucious appearance of improvement.

With regard to the experiments on man, Dr. Elliot relates a number of cases in which the results would seem to show that the action of strychnine was like that of any other cardiae and respiratory stimulant, but that there was any specific antidotal action the author can not admit. In some cases hysteria and fright were strong elements, and in a few cases the histories suggested thanatophidian origin. Dr. Elliot says that he can not accept Dr. Müller's conclusions until he knows of at least one recorded case in which a well-grown poisonous snake struck a man, a woman, or a child; in which that snake was identified by a reliable authority and proved to possess fangs and a poisonous sac, or it was shown that, in another case, a fatal result had followed a bite from this same snake; or in which symptoms of undoubted snake poisoning appeared and were definitely removed by the administration of strychnine. He can not accept cases in which strychnine was given, and, after an indefinite period, "the patient got better." No such cases, he says, are forthcoming, and he thinks that, while experiments on animals condemn, experiments on man do not definitely and distinctly support, Dr. Müller's treatment.

The Employment of Iodoform Vapors in Coryza and Bronchitis.—In the Revue internationale de médecine et de chirurgie pratiques for January 10th there is an abstract of a paper which was read at a recent meeting of the Sociétédé thérapeutique by M. Maurel. The writer remarks that, as the Staphylococcus albus is a micro-organism which is always found in the nasal mucosae, and is capable of playing an important rôle in the pathogeny of coryza, M. Maurel thought that in this disease he could use a product that would act directly against the vitality of the microbe. He therefore chose iodoform, as its activity in hindering the cultivation of Staphylococcus albus had been demonstrated experimentally. At the onset of coryza he fixed a piece of cotton saturated with iodoform in the nasal fossa, which did not provoke either annoyance or irritation. The iodoform vapors were thus brought constantly in contact with the mucous membrane, and the coryza disappeared rapidly without causing descending bronchitis. Together with this treatment M. Maurel uses iodoform pastilles, each containing three milligrammes, and the fumes of six of these are inhaled by the patient every day. In this manner the aspiratory tracts of the patient are influenced by the iodoform vapors. The following conclusions, says the writer, may be drawn from M. Maurel's communication: 1. The iodoform vapors that escape from the cotton rapidly cure acute coryza and prevent descending bronchitis. 2. The latter affection is also quickly anesthetized by these vapors together with the use of the pastilles. 3. This treatment is equally serviceable in articular coryza, but it is powerless against ozena. 4. It would probably be well to use it in tuberculosis of the respiratory tract. 5. The iodoform vapors seem to influence all affections either provoked or complicated by the Staphylococcus aureus or albus.

The Duration of the Contagiousness of Diphtheria.—The Journal des praticiens for January 10th contains an article in which the writer remarks that this question is the subject of much controversy. A young physician, M. Tézanas, recently collected sixty observations of patients who were attacked with characteristic diphtheria, and he divided these cases into three series, and made a bacteriological examination of the products taken from the buccal pharyngeal mucous membrane and from the nasal discharge. The following results were obtained: In the first series, in forty-four cases, the mucous membrane did not present any false membranes and there was no nasal discharge. On bacteriological examination, the cultures showed no bacilli, except in three or four cases where Loefler's bacillus disappeared after four days. In the second series, in five cases the mucous membrane was divested of its false membranes and the nasal discharge dried up. Nevertheless, Loefler's bacillus persisted from twelve to twenty-eight days. In the third series, in eleven cases the nasal discharge persisted, and the cultures with this discharge were positive, although those of the products drawn from the buccal-pharyngeal mucous membrane were negative. The presence of bacilli in the nasal discharge was observed for from five to thirty-five days. These facts, says the writer, lead to the following practical conclusions: 1. In a number of cases the metalsphitheritic contagious cases
with the disappearance of Loeffler's bacillus. Nevertheless, the irritated condition of the baceo-pharyngeal mucous membrane, under the influence of intercurrent measles, favors the increase of the bacilli and their presence in the mouth; hence the necessity of a bacteriologic examination of the products taken from the mucous membrane of this cavity. 2. Not infrequently (in eleven cases out of sixty) Loeffler's bacillus disappears from the throat, but is still found in the nasal discharge. The trouble is thought to be common corzya, which is a mistake, as this discharge is not accompanied with any symptoms of classic corzya. There is no conjunctival injection, or headache, or watering of the eyes. Ordinarily it is unilateral. The discharge is a transparent mucus and by no means the sanguineous discharge which succeeds false membranes of the throat. 3. According to M. Tézanos, Loeffler's bacillus exists in the nasal cavities as long as the nasal discharge continues, and disappears when it does. He adds that when this discharge is absent there are no bacilli in the nose.

In practice, then, says the writer, this fact must be taken into consideration, that a nasal discharge the origin of which does not coincide with the disappearance of the false membranes is not diphtheritic. It does not contain Loeffler's bacilli. The bacteriological examination proves that unquestionably.

The Inconveniences of a Milk Diet in Cases of Albuminuria.—The Revue internationale de médecine et de chirurgie pratiques for January 10th contains an abstract of an article by M. de Grandmouso which appeared in the Médecine moderne, No. 76, 1894. The author, says the writer, has established a distinction in patients suffering from albuminuria, from a therapeutical point of view. If patients attacked with parenchymatous nephritis, or threatened with uremia, whatever may be the renal lesion which causes it, find a milk diet absolutely satisfactory, the author thinks that it has not the same effect in goyty albuminuria. He considers that an exclusive milk diet is useless among patients of this class and even harmful, as it does not furnish sufficient nourishment for persons who have to work, and they form the majority of this class of patients. As uric acid is the irritating product of the glomerules and causes the appearance of albuminuria, the author does not see what influence a milk diet can have on the elimination of the uric acid. He advises that patients of this class should be subjected to the ordinary diet, and that, in certain cases, they should be given tonics—such as iron—or modifiers of vascular tension, such as strychnine, or substances which act directly on urinial infiltration, such as strontium lactate. The gouty diathesis must also be kept in view, and, in instituting an appropriate treatment, "uricaemia" and irritation of the glomerules must be avoided, as they give rise to albuminuria.

Pilocarpine in the Treatment of Nephritis.—In the January number of the Annales des maladies des organes génito-urinaires there is an abstract of a paper which was read at a recent meeting of the Lyons congés de médecine interne by M. H. Mollière. The author had tried this remedy in the treatment of acute and chronic nephritis. The applications consisted of frictions, practiced especially on the trunk, with an ointment composed of three ounces of white vaseline and from four fifths of a grain to a grain and three fifths of pilocarpine nitrate. A very large dose of the remedy, he says, causes disagreeable cutaneous eruptions, which may make it necessary to interrupt the treatment.

The region is covered with a thick layer of cotton wool and a piece of waxed linen, which is not to be taken off until the wool is completely wet with perspiration, when it is replaced at the end of a few hours. In patients who are subjected to a milk diet, as well as in those who take other forms of nourish-

ment, the results are very nearly the same: a rapid recovery in acute nephritis and a marked amelioration in the chronic form.

M. Mollière calls attention to the sudorific action of pilocarpine, which is manifested by a continued abundant sweat, and a concomitant diuresis is accomplished through the medium of the nervous system. In this way medicaments which act directly on the kidneys after being absorbed by the stomach, which they soon irritate and disorder, may be avoided.

External applications of pilocarpine do not directly influence either the kidneys or the stomach, and the revulsive and derivative action on the skin facilitates the elimination of the toxins and at the same time relieves the congestion of the kidneys.

Furthermore, the diuretic action of pilocarpine is added to that of the milk, and, by the sweating it provokes, moderates the exaggerated action, if there is any, which may end by irritating the kidney itself. In the beginning of convalescence, says the author, when the oedema has disappeared and the albuminuria diminished, it is well to have this indirect diuretic action.

The physiological action of pilocarpine, says M. Mollière, applied by friction, seems to be purely local; the medicament is not absorbed, and it is impossible to find any trace of it in the urine. With regard to diuresis, it may be explained by the effects which are obtained in external applications of certain alkaldios. In the same manner that sparteine, when applied to the skin, produces a lowering of the central temperature, so pilocarpine may give rise to a medullary reflex causing the vaso-dilatation of the kidney.

Meningism.—The Revue internationale de médecine et de chirurgie pratiques for January 10th publishes an abstract of a paper which was read at a recent meeting of the Congrés de médecine internationale, of Lyons, a report of which appeared in the Bulletin médical for November, 1894. Under this name the author designated all the symptoms excited by pain in the meningeo-cortical zones, and independent of any anatomical pathological alteration. The elements of meningism are symptoms of general and local excitation, then depression of the cerebral cortex, with headache, vomiting, and constipation, and finally thurmic disorders. A neuropathic heredity is the most important cause. Meningism is observed chiefly in children and young women. Its exciting causes are of a reflex, infectious, or toxic nature. The purest type is presented in hysteria, and it may be considered a form of toxic hysteria.

Umbilical Inflammation.—At a recent meeting of the Société de chirurgie, a report of which appears in the Mercure médical for January 9th, M. Tilliaux related the history of a case which had come under his observation. The patient was a diabetic, and in the umbilicus was a calculus very deeply seated. There had been lymphangitis with the formation of a subcutaneous abscess, which had been opened. M. Tilliaux called attention to the frequency of subcutaneous umbilical inflammation, and said that, although he did not doubt the existence of the subperitoneal inflammation described by M. Huretaux, he thought it was extremely rare, and that, owing to the very deep seat of these subcutaneous abscesses, it had erroneously been thought, upon opening them, that the peritoneum was exposed.

M. G. Marchant had observed two cases of circumumbilical inflammation. In one case the abscess had manifestly been situated behind the sheath of the right rectus muscle. In the other case the abscess had also been subperitoneal, and the pus had contained gonoccoci.

M. Segond had observed two cases of subperitoneal abscess in very stout persons.

M. Riehelot said that he had seen a case where the subperitoneal abscess had been of tuberculous origin, and he thought
that many of the abscesses described by M. Heurtet have been due to tuberculosis.

M. Tuffier also cited a case where the umbilical abscess had been caused by inflammation of the verniform appendix.

A Case of Poisoning with Nutmegs.—In the _Lancet_ for January 19th Mr. T. G. Simpson, L. R. C. P. Edin., relates the following case: On December 9th his assistant was called to see a woman, twenty-six years old. He found her lying on the bed in a drowsy condition and very delirious. There were fairly lucid intervals, when she complained of a sensation of great tightness across the chest and of vertigo and faintness when attempting to rise. She vomited several times. The pulse was 75 a minute and rather feeble; the heart's action was also feeble; the pupils were normal. It was ascertained upon making inquiries that the patient, who was a strong, healthy woman, had taken two nutmegs crushed in a small quantity of gin, as she had gone over the menstrual period for a week. The assistant directed her to remain in bed and to take a little strong coffee with a dessertspoonful of brandy in it every half hour. He also prescribed a mixture of potassium bromide, ammonium carbonate, sodium bicarbonate, spirit of cajuput, and chloroform water [quantities not stated]. The author himself saw the patient a few hours later and found her condition improved, but still showing the same symptoms. He continued the treatment, and the next day she was very much better, although there was a little vertigo, and she was very weak. The coffee and brandy were given up, but the medicine was continued and on the following day she was able to get up. Since then recovery had progressed favorably. The author adds that the nutmegs had no effect whatever in producing miscarriage.

Injections of Sheep Serum in the Treatment of Syphilis.—In the _Presse médicale_ for January 12th there is a review of an article by Dr. Istamanoff, which appeared in _Vratch_ for November 24, 1894. The author, says the writer, tried this method in sixteen cases of syphilis, and in thirteen the injections caused the disappearance of all the secondary symptoms; in the fourteenth, they had no result; in the fifteenth, the symptoms returned as soon as the injections were discontinued; and in the sixteenth, the roseola disappeared, but the ulcerated papules were not modified, so that the author had to resort to local treatment with calomel.

The serum was taken every day from a sheep's carotid artery, and injections of from two to six cubic centimetres were administered every day, or at intervals of two or three days, ordinarily in the buttock. The largest number of injections given to each patient was fifteen. The author found that they were always painful, sometimes extremely so, and that each one gave rise to a slight increase of temperature, which did not exceed, however, 98° F.

With regard to the curative value of this treatment, Dr. Istamanoff admits that the injections cause the disappearance of the visible manifestations of syphilis in the secondary period, but the small number of cases and the short time during which the patients were under observation did not enable the author to say whether or not these injections really cured syphilis and prevented its recurrence.

The Treatment of Diphtheritic Angina with a Concentrated Solution of Corrosive Sublimate in Glycerin.—The _Gazette hebdomadaire de médecine et de chirurgie_ for January 5th contains a review of an article by M. Goubeau and M. Halot, which appeared in the _Archives générales de médecine_ for September and October, 1894. In forty-four cases, says the writer, the authors employed this treatment, which consisted in painting the false membranes with glycerin containing five per cent. of corrosive sublimate twice during the twenty-four hours. The paintings should be confined as much as possible to the false membranes, which should never be detached, and if too much of the sublimate has been used it must be wiped off immediately with a dry brush. These applications were not painful in the majority of cases, and the false membranes seemed to dry in their place and fall off without being reproduced. The secondary infections and the adenopathy disappeared very rapidly, the general condition improved quickly, and no symptoms of mercurial poisoning supervened even in very young infants. The mortality was 4.7 per cent.

The Pithecanthropus Erectus.—In the _Progrès médical_ for January 12th M. Bandouin writes that a biological discovery of really very great interest, if the account is true, has recently been made at Java by M. Dubois, of Holland, and communicated to the _Société de géographie_ and to the _Société d'anthropologie_. This discovery, he says, is nothing less than the finding of the long-sought-for "missing link" between man and the monkey, of the _Pithecanthropus erectus_ predicted for so many years by Darwin and his followers. This, says the writer, is undoubtedly the most important scientific fact recorded for the year 1894. All honor then, he says, to Darwin and to Broca, who many years ago foretold and prepared the world for this magnificent triumph of modern science.

A Treatment for Acne of the Face.—In an abstract from the _Bulletin général de thérapeutique_ for December 30, 1894, which appears in _Lyons médical_ for January 13th, the writer gives the following formula which, he says, has often been employed at the Saint-Louis with success: Fresh lard, 759 grams; sublimed sulphur, 165 grams; beta-naphthol and styrax ointment, each, 50 grams. Applications of this mixture should be made with strong friction every night for a week, then interrupted for six days, when they may be repeated if necessary, although it is often useless to do so. If there is an appearance of small acute clusters, which generally show themselves toward the second day, the acne is ordinarily cured or very much ameliorated at the end of a week.

A New Treatment of Whooping-cough.—_Lyons médical_ for January 13th publishes an abstract of an article from the _Médecine moderne_ for December 26, 1894, in which M. de Chauteaubourg describes a new treatment of whooping-cough, which consists in injecting, subcutaneously, two cubic centimetres and a half of a ten-per-cent. solution of guaiacol and eucalyptol in sterilized oil. After the third injection the fits of coughing diminish noticeably, the appetite returns, and, as the vomiting rapidly ceases and the general condition begins to feel the good effects of the treatment, the whooping-cough disappears at the same time. The author reported five cases.

The New York Academy of Medicine.—At the last general meeting, on Thursday evening, the 7th inst., the special order was a paper entitled _Some Considerations about the Materia Medica and Therapeutics_, by Dr. E. G. Janeway.

At the next meeting of the Section in Genito-urinary Surgery, on Tuesday evening, the 12th inst., a paper is to be read on _The Present Treatment of Urthritis in New York_, by Dr. Ramon Guitéras. Patients and pathological specimens will be presented.

At the next meeting of the Section in Paediatrics, on Thursday evening, the 14th inst., the following papers will be read: The Effect of Primary Schools on the Health of the Children, by Dr. H. D. Chapin; How can the Sanitary Conditions of the Public Schools be Improved? by Mr. Charles C. Welram; and Infectious Diseases in Schools, by Dr. Moreau Morris.
Original Communications.

SPRAINED ANKLE.

A TREATMENT THAT INVOLVES NO LOSS OF TIME, 
REQUIRES NO CRUTCHES, AND IS
NOT ATTENDED WITH ANY ULTIMATE IMPAIRMENT OF FUNCTION.

By V. P. GIBNEY, M.D.,
SURGEON IN CHIEF TO THE HOSPITAL FOR THE RUPERTED AND CRIPPLED.

In the January issue of the New York Polyclinic for 1893 the writer published a paper entitled The Modern Treatment of Sprained Ankle. The interest awakened in the profession by the publication of a method of treatment so simple and so efficient prompts him to make a still further communication. A number of letters asking for more explicit details, mildly criticising the style of the writer, have called for this second edition, which is now presented in the hope that the method advocated may prove as serviceable to the members of the profession as it has to the many who have made themselves familiar with its application.

As stated in 1893, no claim is made to any priority. The aim has been simply to present a method which was first employed, so far as one can learn, by Mr. Edward Cotterell, of London.

Dr. William R. Davis, captain, medical corps of the United States army, was the gentleman who first called my attention to this treatment in 1888, and I should have given him credit for this in Case I of the paper published in the New York Polyclinic, and my only apology for not doing so at the time is that, when I made the report, I had forgotten the initials of the surgeon and also the post at which he was stationed. He assured me at that time that it was not an uncommon thing at the post to put up the sprained ankles of soldiers in this way, and that prompt relief always followed. In a recent conversation with this gentleman he confirms the report then made, and it gives me great pleasure, therefore, to acknowledge an indebtedness so tardily made.

As a preliminary, I can not do better than quote from my former article, as follows:

"I had learned to look upon a sprain as a kind of mystery involving a laceration of fibrous structures about the joint, 'a rupture of the ligament or ligaments,' sometimes a tenosynovitis, sometimes a contusion of the cartilage, but was never able to say which was which, and was inclined to look with a certain degree of admiration or pity on the man who was able to say that this ligament or that ligament was torn or detached from the bone, and I treated my cases as most men do to-day, by fomentations for a little while, then plaster of Paris bandage or silicate of soda, rest on axillary crutches, subsequent rubbing and massage, etc. I confess I was never enamored of this treatment, and I had a grave apprehension always when I took charge of a case, lest I should get a stiffish joint following treatment, an irritable joint—one very much like the joints left after tuberculous disease in children where suppuration has not been a part of the disease. The external features of a sprain, the signs, were always very well pronounced. One could see the puffiness in the neighborhood of the malleolus or over the dorsum of the foot, the localized swelling with extra heat, and sometimes ecchymosis. I was brought to a knowledge of the treatment I am to describe later by the following case."

The illustrations now presented will give one, I think, a fair idea of the details of the dressing. For instance, in Fig. 1 the first strips are applied for a sprain about the external malleolus. It will be seen that a strip of rubber plaster, about twelve inches in length, is applied, beginning at the outer border of the foot, near the little toe, and ending on the inner side of the foot, about its middle, just under the plantar arch. The second strip is applied vertically, and passes from about the junction of the middle with the lower third of the leg, down alongside the tendo Achillis, over the heel, and terminating at a point just above the internal malleolus, but posterior to this.

These strips, by the way, are best shown in Fig. 3, as they hang from a chair or table, and were photographed merely to show about the width and length of the strips as cut. It is not necessary, however, to cut the strips from a sheet of plaster, but they can be easily cut from a spool on which the plaster is rolled any desired length.

The remaining strips are applied in the same way, one
overlapping the other about one half, until the whole external malleolus and side of the foot up to the middle third of the leg is covered, as shown in Fig. 2. It is well to re-enforce just under the malleolus by strips passing criss-cross, so as to give additional support to the part sprained. It is also important to have the strips well overlap each other, especially over the tendo Achilles and about the heel, as any slipping at these points may cause an unnecessary irritation when the boot is applied. The front of the foot with the plaster strips applied is shown also in Fig. 3 on the same plate showing the strips. It will be seen that care has been taken not to completely encircle the ankle, but to leave a space, so that all constriction may be avoided. Fig. 3, therefore, shows the front of the foot with the strips applied to the ankle, shows also the strips hanging upon a table or a board, and ought to be sufficiently clear to enable any one to complete the dressing.

Where the sprain involves the tarsal joint itself, or the midtarsal joint, and where the whole foot is involved in the swelling, the first strips are shown in Fig. 4. The first one starts on the inner side of the heel, passes back of the heel, below the external malleolus, over the dorsum of the foot, and terminates just under the ball of the great toe. The second one is started just under the external malleolus, passes over the back of the heel, over the front of the foot, and terminates just under the outer side of the foot, near the small toe. Fig. 5 shows the complete dressing for a sprain of the kind just described. I sometimes apply extra strips up and down over the tendo Achilles, the ends terminating in the sole of the foot. This precaution I have found necessary to avoid any slipping of the strips about the heel. Over the ankle thus strapped a cheese cloth bandage is snugly applied, beginning at the ball of the foot and extending up to the middle third of the leg. In cases where the toes are much swollen and where the whole ankle must be strapped, and where it is impossible to leave any space uncovered, every toe should be strapped separately before the ankle dressing is applied. This precaution is necessary to avoid swelling of the toes and insure additional comfort to the patient.

Before any strips of plaster are applied, it is good practice to elevate the foot overnight or for a few hours and employ immediate massage of the parts for a few minutes, then apply a roller bandage until one is ready to adjust the dressing. As a matter of fact, however, this precaution is seldom taken, because patients who have come under my care have generally had some preliminary treatment, and the temptation to put them on their feet at once is so great that it is difficult to resist the immediate dressing of the parts. The cases reported bear me out in this statement, and will convince, I think, the reader that the procedure just mentioned is of little importance.

The following cases recorded merely illustrate the efficiency of the treatment in the different classes of sprains that come under one’s observation:

**Case I.**—A clergyman, thirty-nine years of age, from New Jersey, came into my office on the 13th of August, 1894, on crutches, and complaining of pain about the outer side of his ankle and across his instep. I made out as diagnosis a chronic sprain, or, more properly speaking, a subacute tenosynovitis of the peroneal tendon of the left ankle.

The history he gave was that about three months prior to this date he turned on his left ankle and wrenched the ligaments about his external malleolus. The shock was quite severe at the time. The ankle was soon put up in plaster of Paris, which remained on for two or three weeks. Bandaging was resorted to subsequently, rubbing every day, and at the time he came under my care I found a little tenderness and thickening just below the external malleolus and over the cuboid. Any attempt at adduction of the foot produced pain. There was very little extra heat. The other movements of the joint were good. He wore an elastic anklelet. This was removed, and the parts were well strapped in accordance with the illustration as shown in Fig. 1. He was urged to discontinue his crutches and to use the foot moderately.
Feb. 16, 1895.]

GIBNEY: SPRAINED ANKLE. 195

I saw him again on the 29th of August. He was then without crutches, and reported that he had been walking with scarcely any difficulty. He looked upon the relief simply as marvelous. I strapped the parts, though over a smaller area, and referred him to his family physician with the request that he restrap if it were found necessary. The reports subsequently are that he has made a perfect recovery.

Case II.—A gentleman, sixty years of age, living in this city, was referred to me on the 28th of April, 1893. The diagnosis made was sprain of the left ankle, chiefly confined to the lateral ligaments about the external malleolus.

The history he gave was as follows: Four days previously, while walking the streets in Washington, he stepped upon a small round stone, bringing the Shank of his shoe against it, and his foot turned quickly, straining the ligaments on the outer side. He rested for a day or two and had a surgeon in Washington see him, who reported that it was not necessary to do much for the case, that it would soon get well, and that he had better lie up for a few days. He applied some lotions, and after a day or two went to Baltimore, where he walked about a good deal, and returned home with his ankle very much swollen and unable to get about without great difficulty.

At the time of my examination the parts were very much swollen from the base of the toes to the upper third of the calf. The contours of the malleoli were completely effaced. The point of greatest tenderness was about the external malleolus and a little posteriorly. Careful examination revealed no evidence of fracture or dislocation. There was no fluctuation anywhere, simply an edematous foot.

I had him recline on a couch with his foot well elevated and instructed one of his male servants how to rub the foot. Two hours later I applied the dressing as shown in Figs. 4 and 5. On account of his size I took special pains to re-enforce the parts under the malleoli. I made him put his stocking and boot on while I waited. In accordance with my custom I had him walk at once eight or ten laps around the room. He rebelled strenuously at first, but after two or three turns expressed himself as feeling remarkably well. Before I left the house he was walking rhythmically and do his best to dispence with the limp. He was desirous of going on a fishing excursion the next day, and to this I gave consent.

I saw him again on the 2d of May. He reported that he had had little or no pain in his ankle since the adhesive strips were applied; that he went fishing on the 29th, but had encountered an easterly wind, sat in the boat, got cold and very chilly, and was cramped a good deal. The next day he complained of pain in his knees and was quite lame.

I found no swelling in the knees, yet I advised salicylate of sodium and hot fomentations. On removing the adhesive strips I found the swelling reduced to a minimum. In fact, there was scarcely anything to be seen. A little thickening remained about the external malleolus.

I restrapped, leaving the toes uncovered. I failed to mention in the foregoing that I found it necessary to strap the toes at the first dressing by reason of the great swelling. He went down town to his business.

I saw him again on the 9th of May, and was able to discharge the case as cured. I have had an opportunity of seeing him from time to time, and there has not been any relapse or any impairment of function.

Case III.—A lady, eighteen years of age, was referred to me by some friends on the 18th of September, 1894. I found a sprain of the left ankle with this history: That four weeks before she sprained the ankle by turning on it. She consulted a physician in a neighboring State, who assured her that there was quite a severe laceration of the structures about the inner side of the ankle. Splints were employed, and a few days later hot and cold douches were substituted.

She came to me then, at the end of four weeks, walking on crutches. I found tenderness on pressure over the joint in front and to the inner side. There was no swelling of any account. The functions of the joint were limited about one half. The parts were strapped, and she was urged to use the limb and dispense with crutches.

I saw her again on the 24th of September, and she reported herself as very much relieved. She had not used the crutches. A similar strapping was applied, and again on the 11th of October I made a note that she had about recovered. She was able to walk long distances without pain or discomfort, moved the foot in all directions normally; was unable to spring as well on this foot, however, as on the other. She had attempted dancing, and found it a little difficult. I assured her that she would soon be able to dance, applied some small strips about the external malleolus, directed her to wear these for five or six weeks, and permitted her to use low shoes. She made an uneventful recovery.

Case IV.—A lady, about forty years of age, rather stout, from the northern part of the State, was referred to me on the 6th of April by Dr. Willis Ford, of Utica. I found a rather diffuse sprain of the left ankle, the chief point of injury on the outer side.

The day before, while getting out of a carriage, she turned on her ankle and came with her full weight upon the twisted foot. She suffered, of course, a great deal, fainted, and was seen by Dr. Ford, who applied, after a little while, the adhesive strips. As she was coming to New York the next day, he advised her, however, to see me on her arrival in the city. It was difficult, he reported, to get the foot in good position, and he was not satisfied with the dressing as applied.

I found her with the strapping very neatly applied, but with the heel a little too much raised. I took the dressing off and found no ecchymosis, but a swelling about the external malleolus. I made a pretty careful examination in order to exclude fracture or dislocation.

The lady was extremely desirous of sailing for Europe the next morning, and after getting her foot into good position and strapping it well, I urged her to walk about the floor, which she did. I had no hesitation, therefore, in assuring her that she could sail, and that she would make a good recovery.

On the 30th of May, 1894, her brother, one of the most distinguished physicians in this country, reported to me in Washington that he had just received a letter from his sister, in which she stated that she had come to regard the age of miracles as passed, but that since her ankle had been strapped and she had gone to Europe she believed that miracles were still being wrought; that she had had no pain or discomfort whatever in crossing the Atlantic; that she landed and was able to walk with very little disability, and to show how complete her relief was, that she had just made an ascent of Vesuvius and back, feeling almost perfectly well.

Case V.—On the 22d of May, 1893, a gentleman, fifty-three years of age, from New Jersey, was brought to me by Dr. John A. Wells, of Englewood. The diagnosis was of a chronic strain of the left ankle, with a subacute arthritis of the knee, secondary to a fracture of the tibia.

The history given was this: Three months prior to the date of his visit he fell and fractured the left tibia. There was a little overridding. A doctor was found at the time, and the foot was severely wrenched. He put the whole limb up in a fracture box. At the end of a month, when he was about taking it out, the patient, while getting out of bed, strained his left
knee rather sharply, and almost immediately there was swelling in the popliteal space. This continued for three or four weeks rather acutely, and the plaster bandage was applied. The fracture was found to have united in a straight line, but a good deal of thickening remained about the ankle. At the end of two months the dressings were taken off. He was put on a pair of crutches, since which time he had been going about with very little pain and progressive improvement, but it was rather slow. In a previous consultation plaster of Paris was again advised for his ankle, but the patient objected so much to this that Dr. Wells determined to consult an orthopedic surgeon, and hence his visit to me.

I found that the knee presented some thickening around the patella and across either side of the ligamentum patellae, with tenderness just over the articular side of the tibia. There was some tenderness in the popliteal space. He could flex the knee to ninety degrees easily and extend to one hundred and eighty degrees. As the knee was moved in flexion and extension there was a ricto-body sensation imparted to one's hand, and he found this exceedingly difficult to walk. The right ankle measured, just over the malleoli, ten inches; over heel and instep, twelve inches and a half; over instep, nine inches and three quarters. The left, at the corresponding points, nine inches and three quarters, twelve inches and three quarters, and ten inches.

I strapped the ankle for a general sprain, and also strapped the knee. Dr. Wells was very much impressed with the treatment, and agreed to continue the same until a cure resulted.

On July 11, 1893, I find this report on my notes: "Two or three weeks ago the wife called to report that the recovery was about complete; that the adhesive plaster worked like a charm." During the month of December, 1894, now less than a month ago, I casually met Dr. Wells, who reported that the cure in this case was perfect, and that he had treated a large number of cases since that date, after the same plan, with uniformly good results.

**Case VI.**—While dining out on the 22d of January, 1893, a letter came to me from a gentleman, asking that I come to his hotel and treat his sprained ankle. In the latter he stated that his friends, who had advised him to call upon me, assured him that he could go to his business on the following day if I should see him that evening. With such an introduction I proceeded after dinner to the hotel, and found a gentleman, forty-one years of age and a lawyer by profession, suffered from a sprain of the left ankle of two weeks' duration. The ankle was incised in a starch bandage, and he had been using crutches for the past week or ten days.

He acquired the sprain by stepping off a car and turning on his ankle rather sharply. The pain was not great that night, but the following day it was much swollen on the outer side. The opinion was given that day by his physician that he was suffering from a greecestick fracture. The diagnosis was accepted by another physician, who applied a starch bandage and had had him under observation up to the time I was called to see the case.

On removing the bandage, I found that he could move the foot in flexion and extension quite easily and with very little pain, but there existed a tendinous click in the course of the anterior tibial. There was also much tenderness just above the external malleolus and along the tibia. I found no evidence of fracture. There was some swelling and thickening below the malleolus.

The parts were well shaved, rubbed a while, and then strapped with adhesive plasters. He went to his business the next day, and a letter on the 25th of January reported that he was getting on so well that he thought it unnecessary to call. I did see him on the 28th of January, when I found the cure about complete. He made a good recovery, and up to the present time report comes that he has remained quite well.

**Case VII.**—A lady, about eighteen years of age, was referred to me by Dr. William K. Draper, who represented Dr. Kincaid in his absence from the city.

The history given was this: That nine weeks previously, while in the country, she jumped from a rock about forty feet in height and turned as she came to the ground, spraining her left ankle. She was completely disabled by the injury, and in a day or two the foot and leg were swollen from the toes to the head of the tibia. There was considerable ecchymosis on both sides of the foot, and especially over the dorsum. She had had the stereotyped treatment for sprains — hot and cold douches, rest, crutches, etc.

I found the foot bandaged from the toes to the head of the tibia. She was able to flex and extend fairly well, but could not flex quite up to ninety degrees without pain. The pain referred to was felt about the insertion of the tendo Achillis. If she extended the foot fully, she complained of pain in the front, just over the head of the astragalis. The normal depressions under the malleoli were filled with a little infiltration. I could detect no callus anywhere. There was certainly no dislocation. All the toes were very much swollen.

I proceeded at once to strap the individual toes firmly, then strap the whole foot and ankle up to the junction of the middle with the lower third of the calf, aiming to get the foot in a good position as possible and re-enforcing along the malleoli. I had her put on a heel boot at once, and let her walk eight or ten times around the floor. Before the walk was completed she asked to go into the parlor and assist her sisters in entertaining some company. I assured her that she might go out on the morrow for a walk.

On October 15th there was scarcely any swelling about the foot or toes. The parts were restrapped, this time the strapping of the toes omitted. The following notes were made on the 5th of January, 1895: "She reports to-day, and is discharged cured. She has been dancing whenever occasion offered, and the occasions have been rather frequent. She reports that she feels better for the exercise. The plasters are all off. There is no tenderness about the insertion of the tendo Achillis, none over the astragalis. In other words, the functions of the foot are perfect.

**Case VIII.**—On the 25th of December, 1893, a gentleman quite prominent in political circles, thirty-nine years of age, came to me with a tenosynovitis affecting the anterior tibial group, right side.

The history he gave was as follows: "About a week or ten days ago, while walking, he turned on his foot, and it felt a little sore the next day, not at the time. He was horseback-riding a day or two afterward, and this seemed to bring on pain. Within the last day or two he has been pretty lame, and noticed some swelling along his shin."

My examination revealed a thickening along the crest of the tibia — lower portion — a little edema over the muscle, some extra heat, and a little edema as he brought the anterior tibial into play. It pained him to flex and extend. Active and passive movements gave no pain. There was no part of the joint involved.

The parts along the anterior surface of the leg, from the foot to the upper third of the leg, were strapped with adhesive plasters, criss-cross, and a snug roller over all this. He was advised to use his feet naturally, but not to stretch the muscle by too much flexion or extension.
I find on my notes, under January 20, 1894, the following: "He called about ten days after the first visit, and was practically well. There was no tenderness. He could flex and extend the foot very easily. The adhesive strips were taken off and a short stockinet bandage applied." He promised to report if all did not go well. Has not reported. On January 31, 1894, I saw him on the street, and he reported himself as perfectly well.

My brother, Dr. Homer W. Gibney, served a year on the ambulance at the Roosevelt Hospital, and frequently had occasion, both on the ambulance and in the outdoor department of the hospital, to apply this dressing to sprained ankles. At my request he has furnished me with a few cases, brief notes of which are here appended.

Case A.—A man, thirty-four years of age, a plasterer, fell from a scaffolding on the 17th of April, 1893. Was taken to the hospital on the ambulance, and a diagnosis was made of sprained ankle, right side. There was considerable swelling over the external malleolus, ecchymosis, and the parts were exquisitely painful. The ankle was well strapped. He was seen a week later, dressings removed, and relief complete.

Case B.—A man, forty-two years of age, longshoreman, fell from the dock to the lighter on April 19, 1893, and sprained his right ankle. There was great swelling over the internal malleolus. He was immediately strapped and was made to walk. Two weeks later the ankle was re-strapped. He walked easily very soon after the dressing was applied. The case has been dressed recently and cure was found complete.

Case C.—A seamstress, twenty-five years of age, wrenched her ankle while getting out of a car on the 15th of January, 1894. There was very little swelling, but the parts were very painful and tender. She walked into the hospital on crutches. The ankle was well strapped. Crutches were laid aside, and she walked to the car which took her home. Was seen a week later, dressing re-enforced, remaining on for a week or two, when she removed the strapping herself, and has suffered no pain or discomfort up to the present time.

Case D.—A woman, twenty-five years of age, very corpulent, sprained her left ankle, and two weeks later there was found much swelling over the external malleolus; ankle very painful. She wore at the time an ill-fitting plaster-of-Paris bandage. This was removed and the parts were well strapped with adhesive plaster from the ball of the foot to the middle third of the leg. She walked away with very little discomfort. At the end of a week the strapping was renewed, and two weeks later all dressings were removed. There was no pain or discomfort, no impairment of function.

Case E.—A nurse, eighteen years of age, sprained her left ankle in March, 1894. The injury was caused by a fall from two or three steps, twisting the ankle. The parts were exquisitely painful, and there was much swelling two days later when she came under treatment. The usual strapping was employed, crutches were dispensed with, and patient walked home, a distance of three blocks from the hospital. She was seen a week later. The swelling was much reduced, though some ecchymosis and tenderness remained. Restrapped, and at the expiration of two weeks all dressings were removed. There was no pain, no discomfort. She was able to follow her vocation without further restriction.

Case F.—A patient sprained the left ankle in the latter part of 1893. About three weeks later—that is, in February, 1894—she came under treatment for what was regarded as a rheumatic ankle. The usual antirheumatics failed to give relief, and she was obliged to give up her work. The parts were finally strapped, the history of the sprain having then been more fully obtained, and she was able to get about with very little discomfort. Three weeks later she was free from pain and could use her ankle quite as well as ever. There has been no recurrence and no further treatment.

Case G.—A patient, twenty-seven years of age, twisted the right ankle while playing tennis. It was strapped at once by Dr. Ewell, the house surgeon of the Roosevelt Hospital. The swelling promptly subsided. It was re-strapped the following day, and the patient continued his duties with little or no discomfort.

I am assured that at least seventy-five patients have been treated in this way in the clinics about Fifty-ninth Street with uniformly good results. This is the stereotyped treatment in the orthopaedic department of the Hospital for the Ruptured and Crippled, at my clinic in the College of Physicians and Surgeons, and has been for years followed in the orthopaedic department of the New York Polyclinic.

The question is often asked, What is the theory of the method of treatment advocated? It has seemed to me that the equable support given to the tendons and ligaments about the joint results promptly in resolution of all effusion, and that the functions of the tendons and ligaments are thus promptly restored; that use of the ankle is very desirable, and that the cure is brought about by the normal action of the foot.

DOUBLE-MOVABLE MIRES FOR JAVAL-SCHÖTZ’S OPHTHALMOMETER.*

By A. EDWARD DAVIS, A.M., M.D.,
INSTRUCTOR IN DISEASES OF THE EYE, NEW YORK POST-GRADUATE SCHOOL; ASSISTANT SURGEON TO MANHATTAN EYE AND EAR HOSPITAL, ETC.

By the term "double-movable mires" I mean that both mires or reflectors (the graduated and rectangular) move at the same time and to an equal extent, and not one (graduated), as in the old instruments, while the other (rectangular) remained fixed twenty degrees from the center of the arc. The advantage of having both mires move instead of one is that in so doing both mires are kept the same distance from the center of the arc, and their images the same distance from any point on the cornea that is being measured; whereas, as the old instruments are constructed, one mire (rectangular) remains fixed at twenty degrees from the center of the arc on one side, while the graduated mire on the other side is required to do all the moving. This is very well if the point on the cornea happens to be of just sufficient radius of curvature in the meridian being measured to allow the image of the movable graduated mire to just touch the image of the rectangular mire when the graduated mire reaches the twenty-degree mark on its respective side of the arc. The mires would then be at an equal distance from the center of the arc, and their images consequently at equal distances from the point on the cornea measured. If, however, the meridian of the cornea under measurement is of such radius of curvature as to allow the

* Presented before the New York Ophthalmological Society, February 12, 1894.
graduated mire to come closer than twenty degrees on its respective side of the arc before the images of the mires touch, its image must necessarily be formed on the surface of the cornea nearer the point measured. On the other hand, if the meridian under measurement is of such radius of curvature that the images of the two mires approximate before the graduated mire reaches the twenty-degree mark on its side of the arc, then its image will, of course, be formed on the surface of the cornea at a greater distance from the point measured than the image from the rectangular mire, which is fixed at twenty degrees on the opposite side of the arc. I think my point is clear. Now, since the human cornea (its apex, or point on it where the visual line intersects its surface) is never, or very rarely, of just the radius of curvature to allow the graduated mire to come exactly to twenty degrees on its respective side, the same distance as the fixed mire on the opposite side, in order to have the images touch, any improvement that keeps both mires at the same distance from the center of the arc in every case, whatsoever the curvature of the cornea may be, is a decided advantage. The double-movable mires accomplish this perfectly.

Those who are only fairly well acquainted with the use of the ophthalmometer are aware of the fact that not the whole of the cornea is measured in an ordinary ophthalmometric examination, but only a very small portion of it—a space only of two and a half to three millimetres in diameter. Furthermore, the center of this space does not coincide with the center of the cornea, except when the visual line coincides with the long axis of cornea, but with that point on the cornea intersected by the visual line, which point is usually a little to the nasal side of the center of the cornea, and as a rule on a horizontal line with it. Or, again, this point may lie to the temporal side of the corneal center. The space included between this visual line and the optic axis forward from the point where they cross is the well-known angle alpha, which is positive, nil, or negative, accordingly as the visual line lies to the nasal side of, coincides with, or is to the temporal side of the optic axis. When the angle alpha is nil or very small, as it is in the majority of cases, the center of the small space measured on the cornea practically coincides with the center of the cornea, and the measurements of the ophthalmometer in such cases, with the proper restrictions as laid down by Javal, agree usually with the glasses accepted by the patient. When, however, this angle is large, especially when there is a large amount of astigmatism, and this associated with a high degree of hyperopia or myopia, the readings of the ophthalmometer do not correspond so closely with the subjective test. For example, in the natural eye with a radius of curvature of eight millimetres, an angle alpha of six degrees is 0.9 milli- metre, or practically one millimetre, and with an angle alpha of twelve degrees it would, of course, be two millimetres (Fig. 2). In such case, therefore, the point on the cornea measured by the ophthalmometer would be two millimetres distant from the center of the cornea to the nasal or temporal side, accordingly as the angle is positive or negative. Now, the two chief radii of curvature at this point may be considerably different from the radii of curvature at the apex, either one or both of them. To simplify matters, we will assume that the radius of curvature changes in but one of the chief meridians, that of the vertical, while it remains unchanged in the horizontal. Let the radius of curvature of the horizontal meridian at the apex be eight millimetres, and that of the vertical meridian 7.61 millimetres. According to Javal's formula, \[ D = 1,000 \left( \frac{n - 1}{r} \right) \] the astigmatism at the apex in such case is two dioptres. Say, however, at two millimetres distant from the apex the radius of curvature of the vertical meridian changes from 7.61 millimetres to 7.31 millimetres, while the radius of curvature of the horizontal meridian remains the same as at the apex. According to the same formula, \[ D = 1,000 \left( \frac{n - 1}{r} \right) \] the astigmatism at this point would be four dioptres. The difference in the amount of astigmatism at the two points would clearly be two whole dioptres. Of course this is a much exaggerated case, but it serves to illustrate how a large angle alpha may affect the readings of the ophthalmometer, and how the astigmatism at the apex of the cornea may vary from that at the point on the cornea intersected by the visual line. This error holds against the double-movable mires as well as the single-mov-

---

* Practically the same as the optic axis.
able mire, but not to the same extent, and for this reason:
Besides having the radii of curvature of the two chief meridians differ, which difference is the amount of astigmatism present, the radius of curvature may be different in one and the same meridian, and not necessarily have marked irregular astigmatism, as in low degrees of conical cornes, or even where there is no conical cornea, it being a
well-known fact that the farther we go toward the periphery of the cornea the flatter its surface becomes.
This slight change* of curvature in the same meridian may be present in one or both of the two chief meridians of curvature. Moreover, the further away from the point being measured, the greater the differ-
ence in the radius of curvature in the same meridian is likely to be. Herein, in fact, lies the advantage of double-movable mires over the single-movable mire.
With double-movable mires both images remain the
same distance from the point on the cornea under measurement and relatively closer to it than in the single-movable mire. For, as has already been pointed out above, in the instrument with the single-movable mire one mire must remain fixed at twenty degrees from the center of the arc, while the other may be nearer to or further away, accordingly as the radius of curvature happens to be longer or shorter than 8.38 millimetres, the radius of curvature of the cornea (and the only one, by the way), which, by Javal’s old instrument, allows the movable mire to be exactly the same distance from the center of the arc (twenty degrees) as the fixed mire is, and the images touch. If shorter than 8.38 millimetres, both images will become smaller, and to a relative extent, if the curve is constant, and the movable mire would have to be displaced further than twenty degrees on the arc in order to have the images just ap-
proximate. And if the surface of the cornea, from which this image of this relatively too-far displaced movable mire is reflected, happens to have a radius of curvature (in one and the same meridian) slightly shorter than that point on the cornea from which the image of the fixed mire is reflected, then the image from the movable mire would be actually smaller than that from the fixed mire. Again, if the radius of curvature happens to be longer than 8.38 millimetres, both images will be larger, and the movable mire would have to be moved closer than twenty degrees in order to have the images touch. Consequently, the image from the fixed mire in this instance, if the surface from which it is reflected is shorter in radius of curvature than that from which the image of the movable mire is reflected, will be actually smaller than that from the movable mire.
Conversely to both of the above-cited cases, and as most often happens, when the radius of curvature of the surface of the cornea from which the image of the relatively too-far-displaced mire is reflected is longer than that from which the image of the relatively too close mire is reflected, the amount of astigmatism as measured by the single-
movable mire is greater than when measured by the double movable mire. Furthermore, other things being equal, the further removed this image of the relatively too-far-displaced mire from the center under measurement, the greater the change in the surface of the cornea is likely to be, with, of course, a resultant increase in the error. With
double-movable mires this error does not obtain to the same extent as with the single; hence the advantage of the former over the latter. However, if there was no advantage in this respect, it is plainly a desirable thing to have both mires move and kept an equal distance from the center of the arc, and their images equidistant from the center on the cornea under measurement.
In a year’s experience with the double-movable mires I have found in astigmatisms of a comparatively small amount—from one to four dioptres, with little or no hyper-
opia or myopia, and the angle alpha nil or very small—that the readings differed but little from those of the single-
movable mire, the readings with the double-movable mires most of the time being less than with the single movable mire, about 0.25 D. to 0.50 D. less. On the other hand, in astigmatisms of large amount, especially when associated with high degrees of hyperopia or myopia, where the angle alpha is usually large,* the readings have differed more, often as much as half a dioptre and sometimes as much as one dioptre, the double mires usually giving the less amou.
Furthermore, the subjective tests corresponded closer with the readings of the double mires than with those of the single-movable mire.
In irregular astigmatisms the readings with the double-
movable mires proved much more satisfactory than the readings with the single-movable mire.
The modulus operandi of the double-movable mires con-
ists in a thumbscrew attached to the arc on the same side as the graduated or movable mire, about two inches from the telescope. On the attached end of this screw are cogs, into which other cogs, on slender shafts which extend to each mire, play (Fig. 4). Thus, by a simple turn of the

* When it is remembered that exactness to the fraction of one one-
hundredth of a millimetre in measuring the radius of curvature of the cornea is demanded, the importance of noticing even slight changes of curvature in the same meridian will be apparent.

* The angle alpha in these cases was measured with candle and perimeter.
screw, both mires are moved at the same time to an equal extent in or out and at pleasure. In this way both mires are kept the same distance from the center of the arc in every case.

Having both mires move at one time necessitates the regraduation of the arc, both for radius of curvature and for dioptries. The regraduation for the radius of curvature is obtained by the formula: \[ R = \frac{2D I}{O - 1} \] where 0, the object, which in Javal's instrument is the imaginary line between the inner edges of the reflectors or mires; I, the size of the corneal image, which is constant and equals 2.95 millimetres; D, the distance of the object O from the cornea, also a constant quantity—five hundred and sixty millimetres—being double the focal distance of the objective, which in Javal's instrument is two hundred and eighty millimetres.* To obtain the radius of curvature to be marked in millimetres on the inner edge of the arc, corresponding with the twenty-dioptre mark on the posterior edge of the arc, we have \[ R = \frac{2 \times 280 \times 2.95}{200 - 2.95} = 8.38 \text{ mm.} \] and so on, as low down as six and as high up as forty-six respectively on each side of the twenty-dioptre mark, the radius of curvature ranging from thirteen millimetres for the six-dioptre mark to five millimetres for the forty-six-dioptre mark. This doubles the width of range of the single-movable mire, and is of service in conical cornea or in very high degrees of astigmatism sometimes present after cataract extraction.

To regraduate the posterior edge of the arc for the new dioptre marks, it is only necessary to begin at the twenty-dioptre mark as it now stands, and, going each way, divide the dioptre spaces in halves, giving to each half the same value that the whole space now represents, and number them accordingly. For example, where twenty-one now is, twenty-two should be placed; where twenty-two is, twenty-four, and so on; and on the other side of the twenty-dioptre mark, where nineteen now is, eighteen should be written, and where eighteen is, sixteen, etc. (see Fig. 4).

In closing, I wish to thank Dr. G. W. Grove for his valuable suggestions and aid; also Mr. E. B. Meyrowitz, who not only made the improvement, but in a great measure is responsible for the idea of *double movable mires."

The Employment of the New Mydriatic Scopolamine.—Pochmann (Ann. d'oc., June, 1894) regards scopolamine as superior to all other mydriatics, and the bromhydrate as the purest and best preparation. It is five times stronger than atropine, and he uses it in a solution of 1 to 1,000. It is particularly to be recommended in iritis on account of its energetic and sedative action. It breaks adhesions and cuts short the duration of the disease.

A CASE OF CILIARY WOUND FOLLOWED BY SYMPATHETIC IRRITATION.

CLINICAL HISTORY AND ENucleATION.

By DAVID WEBSTER, M. D.

PATHOLOGICAL REPORT AND REMARKS.

By H. DAVISON SCHWARZSCHILD, M. D.

A married woman, aged thirty-five years, was admitted to my clinic at the Manhattan Eye and Ear Hospital on September 26, 1893. She said that on September 20th she had been wounded in the right eye by the small blade of a pocket knife. The wound commenced in the cornea at a point corresponding to the infero-nasal border of the pupil and extended downward and slightly inward, involving the entire width of the ciliary region. The eyelids were slightly swollen; the conjunctiva deeply injected; the pupil irregularrly dilated. There was very little pain either at the time of the injury or subsequently. R. V. = shadows. L. V. = \( \frac{25}{2} \). Atropine was applied, and the patient was advised to remain in the hospital. She entered the hospital as a house patient the next day and was put bed, fed cloths and atropine were applied. After a few days the treatment was changed to bathing the eye with hot water for fifteen minutes every two hours. On October 2nd the patient had improved so much that upon her solicitation she was allowed to go home. The vision was tested and found to be, R. V., perception of light. L. V., \( \frac{25}{2} \) without a glass; raised to \( \frac{25}{2} \) with + 1 D. c. ax. 90°.

I saw the patient at my office on December 12th. A plastic cicatriz had set in, building up a yellowish-white mass behind the lens, and abolishing perception of light. There were blood-vessels converging from the infero-nasal quadrant of the conjunctiva to the cicatrix. The latter was slightly depressed, as though a circumscibed atrophy were beginning. The eyeball was soft, tension = 3. L. V. = \( \frac{25}{2} \); \( \frac{25}{2} \) with + 0.75 D. The left eye was watery and slightly sensitive to light. This was believed to be due to sympathetic irritation. On December 13th she was again admitted as an in-patient; ether was administered and the offending eye was enucleated. It was placed in Müller's fluid and given to Dr. H. Davison Schwarzschild for macroscopic and microscopic examination.

The left eye improved rapidly after the enucleation of the right, and the patient was discharged on December 17th. She wears an artificial eye with comfort.

Pathological Report and Remarks.—The eye showed marked diminution in tension, and a linear scar was visible at the sclero-corneal junction infero-nasally. A gross examination of the frozen section reveals a detached retina, coagulated exudation in the vitreous chamber, and an apparently organized membrane immediately posterior to the lens. The continuation of the cicatrix is seen to the external portion of the ciliary body, the path of the incision being directly backward and outward,—i.e., referring to the sclera, not to the position of the eye in the orbit. The chord subtends an arc of 30°.

Microscopically.—The cicatrizal tissue is well formed and dense. The ciliary body has been the seat of a plastic inflammation and has given rise to the exudation, which is composed of fibrin and is moderately rich in cells, forming a false men-

*This is the focal distance given by Dr. Sulzer; also 2.95 millimetres is the size of the corneal image given by this writer in his description of Javal's instrument (Description de l'ophthalmometre Javal et Schutz, modèle 1889, par le Docteur Sulzer, de Winterthur).
brane in certain areas. The iris at its root is somewhat edematous. The retina is enormously hyperplastic and in parts hemorrhagic. The choroid is atrophic and the optic nerve is almost imperceptibly involved, an extremely slight increase in the number of the connective-tissue nuclei and a moderate dilatation of the vena centralis being the only changes. By appropriate staining small colonies of the staphylococcus are visible in the ciliary body and the anterior part of the exudation.

This case again calls forth discussion on the subject of sympathetic inflammation. The same views which I expressed nearly two years ago I reiterate, if anything, even more emphatically.

The presence of bacteria has nothing whatever to do with the transmission of the inflammation from globe to globe. As a matter of fact, an eye which is full of pus rarely, if ever, affects its fellow-organ, the tendency being toward perforation and secondary atrophy. A highly infected penetrating instrument will be more apt to produce a violent panophthalmitis than a smouldering fire; on the other hand, an aseptic instrument injuring the ciliary body will occasion a plastic cicatrix and sympathetic ophthalmia.

As a result of microscopical examination in cases of sympathetic disease, I find that the ciliary body is intimately connected with the exudation, which is usually more or less fibrinous; the latter exerts traction on the ciliary processes and irritates the nerves, producing the inexplicable reflex.

The iris and ciliary body are also very frequently incarcer-ated in the ciaotrich, producing a constriction of the nerves. Although the optic nerve is in many cases involved in the exciting eye, the lesion in the sympathizing one is an irido cyclitis of varying intensity, and but rarely an optic neuritis. These few latter cases have fostered the theory of direct transmission via the vaginal sheath; but the involvement of the iris and ciliary region can never be explained thereby. Sympathetic inflammation is most likely to occur about six weeks after the reception of the injury; it may occur sooner, and sometimes not till ten years later, particularly if there be an ossific plate in the choroid. It may be stated in general terms that if one eye is affecting the other, the former should be removed.

If, when we see a patient for the first time, both are more or less equally diseased, it is not advisable to enucleate either at once, for sometimes the sympathizing one becomes blind and the other improves. In certain cases the first eye may suffer from serous cyclitis or a moderately subacute iritis with or without traumatic cataract, and the other have well marked sympathetic symptoms; here also both should be symptomatically treated, and we should temporize and keep up a careful surveillance of the eyes. The exciting eye, if blind or so badly affected that we can not hope to obtain useful vision, should be enucleated.

Naturally, the best results are obtained by removing the globe when the sympathizing eye is just entering the prodromic period (sympathetic irritation), and the longer we wait, ceteris paribus, the worse the prognosis.

Contrary to the generally accepted view, it is possible, even after sympathetic inflammation has developed, to cure it by enucleating the exciting eye.

THE RELATION OF THE FUNCTION OF ACCOMMODATION TO THAT OF CONVERGENCE.*

By GEORGE T. STEVENS, M.D.

The views of no man have been more universally and more unreservedly accepted than those of Donders, the revered investigator and pioneer in modern ophthalmology, to professional admiration and for whom has been added personal devotion. Nevertheless, as new facts are added to our knowledge it is certain that some of the doctrines taught by this close and candid observer may be fairly investigated anew in the same spirit of candor which he originally brought to their consideration.

Donders affirms the proposition in regard to the relation between the accommodation and the convergence of the visual lines, that "so far as the range of accommodation for both eyes extends, the state of the accommodation of the eye corresponds to a definite convergence of the visual lines."

Donders, however, did not teach that this connection was absolute and casual, as and some of his predecessors in the same field of inquiry. He recognized the fact that under certain circumstances the relation between the two functions can be "at least partially overcome."

It is well known that in case of complete paralysis of accommodation occurring suddenly in young persons, the function of convergence remains undisturbed, and every one is perfectly familiar with the case of the gradual loss of accommodation from presbyopia with no loss of converging ability. The converse condition—paralysis of the converging muscles with immunity of the accommodation—presents greater difficulties in examination; yet we can not deduce a conclusion from the known facts of this condition in favor of any organic relation between the two functions. Cases long since reported by von Graefe, and many cases reported by others since then, clearly show that accommodation is retained in paralysis of the interni and in ophthalmoplegia externa.

The more recent investigations of the anatomy of the nerves controlling these functions show not only that the nucleus controlling the function of accommodation is distinctively separated from that governing the convergence, but that the nerves from each root pass separately out from the brain and that they are only united within a common sheath after they have traversed a considerable space as separated cords. All these considerations suggest that these two functions, which usually act in close agreement, so act as a result of habitual, not of organic association. In such a case, training, or a necessity which intervenes important obstacles to the habitual association of action, quickly enables the individual to dissociate the two functions absolutely.

The practical issue of this paper is the consideration of this subject from the standpoint of the important deduc-

* Read at the International Ophthalmological Congress, Edinburgh, August 10, 1894.
tions which Donders draws in regard to strabismus. These
deductions are familiar to all, but I will repeat them. They
are formulated by him thus:

"1. **Strabismus convergens** almost always depends upon
hypermetropia.

"2. **Strabismus divergens** is usually the result of my-
opia."

The argument is based upon the necessity of extraor-
dinary tension of the accommodation in hyperopia, and
therefore of the necessity of a correspondingly excessive
tension of convergence, which at length results in perma-
nent contracture of the converging muscles.

Consideration of the facts already mentioned does not
sustain this line of argument, and only a single fact remains
as an apparent confirmation and proof of this important
and ingenious doctrine. This fact is the interesting and
unquestioned one that with the application of convex
glasses the converging strabismus, in a certain proportion
of cases, disappears, at least in some measure, to return
immediately upon the removal of such glasses.

Such a striking fact can not be regarded as a coinci-
dence, and as convex glasses applied to hypermetropic
persons are supposed to have no especial office except
to relieve the accommodation, the deduction is easy and natu-
ral that relieving the accommodation also relieves the
tendency to squint. But the assumption is not correct
either in respect to the result of accommodation upon the
convergence or in respect to the action of the convex
lens. Three essential facts must be considered:

1. Converging strabismus is, in not a few instances, the
result of the instinctive effort to force the visual
lines into the same horizontal plane in case of a normal
tendency of one of these lines to rise above the other.
This condition of hyperphoria, or perhaps of hyperptropia,
in which the image of one eye tends to appear above the
other, or actually rises above, is a condition for the relief
of which the subject will make the most strenuous efforts.
So long as it is not overcome, the patient must acquire the
faculty of mental suppression of one image—a result most
easily obtained when the images are widely separated by
decided squint—or see all vertical objects as though they
were leaning. His own equilibrium depends upon the
apparent equilibrium of surrounding objects. The instinct
therefore to correct an apparent inequality in the height of
the images seen by the two eyes is most urgent. In many
such cases the patient, in the effort to reduce the images
to a horizontal plane, willingly sacrifices single vision in
that plane, and converging strabismus results.

I have elsewhere discussed this subject, and can not here
enter into the details further than to assert that in an
important proportion of cases of convergent strabismus a
tenotomy properly done upon a superior rectus and result-
ing in bringing the images of the two eyes to the same
horizontal plane will at once and without further procedure
relieve the convergent squint.

2. In many instances it is a result of an effort to bring
both eyes to a plane differing from that to which they nor-

vertically acting muscles of one or both eyes that convex
glasses have the effect of relieving the squint.

3. Another essential fact in relation to the relief ob-
tained in this respect from convex glasses is that such a
glass acts in a double capacity, and that its role in relieving
strabismus is not in its capacity for relieving accommoda-
tion, but in its character as a combination of prisms. If a
pair of convex glasses is placed before the eyes of one of
these people, a close observer can in some instances detect
at once the fact that one of the eyes seeks the position
above, the other the position below the center of the lens,
or at least lower than the first. Many photographic por-
traits which I have made show this phenomenon beauti-
fully.

In this manner the images may be more easily brought
to the horizontal plane. Let it be remembered that in a
glass of 3 D, the passage of the line of vision a third of a
centimetre above or below the optical center is equal to the
use of a prism of one degree, and that two such glasses
will serve as a very material aid in maintaining horizontal
images, and that hence the tension in this respect being
relieved, there remains less occasion for the extreme con-
vergence.

The fact that this may be the action of the convex
glass is shown by another fact—namely, that we may re-
move the spherical glasses and replace them by prisms with
their bases up and down, and the effect is equally striking.
This has not happened in every instance in which I have
made the experiment. It is an advantage of the spherical
glass that the patient may adjust the eyes to a certain de-
gree of prisms which is not so easily determined by the sur-
geon, and again it is quite possible that the improved sight
in some of these cases tempts the eye to seek the relief to
the hyperphoria through the glass, as the prism alone does
not. However that may be, I have found the prism to fail
only in such cases as required the aid of the glass to obtain
fairly good vision. Further, a strong cylinder with its axis
horizontal or nearly so, if it serves to clear the vision by
correcting an astigmatism, acts as readily in relieving some
strabismus cases as does a spherical glass in cases of pure
hypermetropia; and it is also true that in some of these
cases concave glasses are quite effectual in relieving the
squint. There also occur many instances in which both eyes
devote vertically, and in the same direction, either equally
or unequally. If we place in such a case a small card be-
FORE one eye in such a way as to exclude it from fixation,
the excluded eye may be seen to rise or fall as the case
may be in a very marked manner. Transferring now the
screen to the other eye, its behavior is similar to the first.
If the first rose behind the screen, the second also rises.
Such cases of double vertical divergence, as the result of
the excessive tension on the opposing vertically acting recti,
will often cause the eyes to squint inward, and a relief to
this tension, either by prisms symmetrically placed or by
relaxation of the excessive tension for both eyes, will also
relieve the tendency to squint inward.* In such a case a

* This visible deviation is not essential to our knowledge of the
excess of tension of the vertically acting muscles; indeed, it is only
found in cases of gross deviating tendencies. Nor is the patient always
pair of strong convex glasses may act as two vertical prisms placed with their bases in the same direction.

In many hundreds of cases in which there have existed great or small deviations of the visual lines, and in which determinations as accurate as could be made of the deviations or deviating tendencies before and after the employment of atropine, I have found no such uniform difference in the muscular conditions before the use of atropine and after the accommodation has been paralyzed as to lead to the suggestion that any change is to be expected in these two conditions beyond the incidental and entirely temporary disturbances which may be brought about by the sudden admission of much light through a dilated pupil or the indifferent adjustments sometimes made by persons not seeing clearly. The disturbances of balance are quickly eliminated by calling the attention of the patient to the necessity of recognizing exactly what is seen. If cures of slight cases of strabismus have occurred under the use of atropine or of escirine, the relief has come, in my opinion, from the inability to see clearly, thus enabling the patient to tolerate a slight confusion of images vertically and not from the relaxation or the stimulation of the accommodation.

There occurs in some cases of moderate esophoria a slight exophoria when strong convex glasses are applied; but while such exophoria may be indicated by the photometer, the power of abduction is not generally increased. In these cases either a hyperphoria or a double vertical anomaly exists or the glasses, by virtue of the distance between their optical centers, act as prisms with the bases out. I have found no case which did not come under one of these two classes.

There is neither time nor necessity to go into statistics in regard to the views here presented. They are based upon close and practical observations of many hundreds of these cases, and I am sure that they will stand the test of critical examination. The conclusions at which I have arrived, from my study of this subject during many years and from abundant material, may be summarily stated in the following propositions:

1. There is no essential connection between the function of convergence and that of accommodation; such connection as exists is incidental and the result of habitual association of the two functions.

2. The proportion of the cases of converging strabismus associated with hypermetropia, and of diverging strabismus associated with myopia, has been greatly exaggerated.

3. That the cases of strabismus which are relieved by positive or negative spherical glasses are cases of hypermetropia—that is, of a deviation of one visual line above the other, or of a deviation of both eyes upward or downward—and that the relief obtained through such glasses is largely through the action of such glasses as vertical prisms.

4. My observations have led me to believe that excessive accommodation is not directly a causative influence in converging strabismus.

33 West Thirty-third Street.

THE INFLUENCE OF THE EYE ON CHARACTER AND CAREER.

By JUSTIN L. BARNES, B.S., M.D.,
ASSISTANT SURGEON TO THE MANHATTAN EYE AND EAR HOSPITAL; ADJUNCT PROFESSOR OF OTOLARYNGOLOGY, UNIVERSITY MEDICAL COLLEGE; FELLOW OF THE NEW YORK ACADEMY OF MEDICINE, ETC.

Why is it that so many children wear glasses nowadays? Is it because their eyes are not so good as were the eyes of their parents? Or is it because more is known about the eye than formerly, or that modern habits and occupations tax vision more severely than in the days of our forefathers?

Almost daily the oculist is asked such questions as these, for the enormous and increasing average of specified children now to be seen in the streets and shops and in our schools and homes is at last, and none too soon for the gravity of the interests at stake, attracting the layman's attention, the attention which has to be arrested and educated before remedies or reforms can be made widely effective.

The oculist is aware that this condition of affairs is increasing, but it may be pointed out at once that while this state of things calls for prompt and most serious consideration, it does not imply necessarily a proportionate decrease in visual power and quality, but a decrease indicated by many modifying factors; among them, on the one hand, the superior advantages and facilities, the better knowledge—more varied and more exact—of to-day; on the other, the multifarious mischief which bacterialize our civilization. Many more children of former generations would have worn glasses but for ignorance, since outlived, and many of the children now wearing them are victims, not of necessity, but of either their own or some other's violation of now well-understood laws. Then, too, city life—with its swift-shifting glimpses at short ranges, frequent and abrupt variation of range, its smoke and dust-veneered medium of vision—subjects the eye to more continuous and more complex strain than do the long ranges, comparative monotony of view, and the serene, breeze-cleansed expanses of the
country; and we tend more and more to cities, and to enormous cities.

Ophthalmology is a young science. Scarce thirty years ago (and even yet in some quarters still prevailing) the common notion was confined to hunting up, in the latter years of maturity, a pair of "specs" with which to read or sew, and to the old unintelligently patient recognition of the defect without thought of a remedy (regarded, too, on the whole, as being, at any age under fifty, an affection or a megrim), as a condition too much a matter of course for sympathy, as an inevitability, like old age or death.

But investigations and experiments in the study of the eye have been so rapidly and conspicuously advanced by the same impulse of progress which has marked this brief period in all departments of science, with results of such peculiar value and brilliancy, that to day it is practicable, as well as obligatory, for the profession to so present the science of sound vision to the general public that the possession of it will be seen to be one of the chief determinative factors in the formation of character and in the selection of occupation; and therefore the question of how to possess and conserve it becomes a consideration of the first magnitude in its bearing on the development of the individual and his particular share in and contribution to communal development.

In asserting for the influence of the eye such extraordinary importance I am not ignoring other—and some in themselves even greater—agencies in the shaping and outcome of human affairs, such as heredity, early impressions, associations and training, well-guided or neglected adolescence, happy or ill-assorted marriage, profligacy, misogamy, and the both far-reaching and close-pressing effects of the struggle for food and shelter which, from cradle to grave, marks the passage of most lives. But these great agencies have received and are (in augment) still receiving such careful and enlightened consideration that both history and philosophy and, in a more signal influence manner, fiction, alike bear its stamp *imprimis*. Yet it may be said of every one of these agencies in respect of their degree and kind of effectiveness, that they are in a first and notable sense in the lead of the eye, since what we really see or what we think we see (and negatively, with very positive effects, what by defect of vision we do not see) has (first, last, and always) an influence upon feeling, thought, purpose, and action—upon our whole decision and conduct, as inevitable as that of breathing upon life, and almost as unconsciously noticed. Consistently, then, it is in order for the oculist to preach his sermon from the ancient, not yet transcended text, "Let there be light!"

Something is very much the matter with our eyes. The evil, whatever its cause, is here, and in the present generation more or less established. In the case of our children it is possible to devise means for mitigating and reducing it, and perhaps also possible that its transmission to the unborn may be checked, if not to a large degree prevented.

In my limited space I shall do my best to express myself clearly, not expecting so much to present anything new or original as to draw and fix attention to what is already known or becoming so, and to present the subject in a new light. This will, I earnestly hope, for the sake of its bearing upon human welfare, especially of children, enlist the sympathy and organized co-operation of physicians, parents, and legislators.

The phenomena of physical and mental vision are so generally understood that they may for present purposes be briefly stated as follows: The purely mechanical reception and transmission of rays of light; the physiological action upon them by the dioptric media (cornea, aqueous humor, lens, and vitreous body); the production of image impressions upon the retinal membrane, and, through the agency of the optic nerve, the transportation of these impressions to the brain—constitute physical vision. The ensuing psychological analysis and interpretation by the brain of images or impressions taken from the previous actual physical sight, or conjured up by correlation and then projected from within the mind, constitute mental vision. In other words, the eye itself is the purely mechanical register of externalities, upon which the mind, assisted by its agent, the brain (through its media of communication, the multitudinous fibers of the sensitive retina and optic nerve), deliberates.

In a pair of normal eyes the leading elements in the physical visual act are two in number. First, "accommodation," by which is meant focusing—accomplished in each eye individually and in a measure independently; second, "adjustment"—that is, a joint muscular act of the two eyes, controlling the direction of the gaze in order to "fix" the sight upon a given point. For instance, in looking at this page each eye must focus upon the print in order to see distinctly, and both eyes must, in interrelation, be properly adjusted in order to secure single vision.

The relations between these two factors are so interdependent that single vision depends upon a nicely calculated and exercised exactitude and reciprocal harmony in their functions, and thus it follows that acuteness and singleness of vision can be maintained only upon one point at a time. This is easily illustrated by simultaneously holding a finger of each hand in a direct line outward before the eyes, the one being held at a greater distance from the eyes than the other; then, on looking fixedly at either one of the fingers, it will appear single and distinct, the other seeming to be double and more or less indistinct, and the converse of this experiment is equally true.

This associated normal action between the eyes—i.e., a condition in which single images are seen, both eyes operating simultaneously, termed by science binocular single vision—secures the correct perspective perception so essential to the estimation of distance, proportion, size, capacity, etc., simply indispensable to success in a large class of the absolutely necessary occupations of life. The stereoscope illustrates this. In this mechanism, as is well known, are two pictures seen as one in full natural perspective. In accomplishing this result, the negatives (which are not, as they seem, exact duplicates) are taken from two slightly separated points of observation, representing the angle of ocular adjustment. These images are fused into one scene.
by prisms so placed as to throw the impressions of the photographs upon such symmetric portions of the retina as will induce a muscular ocular adjustment coincident with that produced by the mind's estimate of the actual proximity or remoteness in fact of the objects represented by the photographs—our estimation of size being calculated upon our notion of the distance involved.

Want of harmony in the binocular relations results in one or more of several conditions, to wit: First, single vision, but maintained with difficulty; second, permanent or constant vision in one eye, while in the other there is continual or intermittent suppression of its visual images; third, alternate vision—i.e., both eyes capable of seeing, but doing so one at a time; fourth, diplopia or double vision. Of these troubles, the last only usually receives attention, because it manifests itself so annoyingly in confusion of vision, while the other three conditions, of even graver importance, may be suffered from unconsciously, for permanent vision in one eye or alternating vision in both eyes, if sight is excellent in the acting eye, is liable to escape notice. The disorders to which these conditions are certain eventually to give rise, fail even of warning, because ignorantly attributed to other causes. This is one among the many strong arguments why regular and frequent professional examinations and treatment of the eye should be secured to all children, especially school children, without regard to the financial, social, or intellectual status of parents or guardians.

When, by reason of any inharmony of function, one eye is developed at the expense of the other, not only do both eyes suffer from the strain imposed, but serious accident to the better eye means practically the loss of both; and impaired vision or total blindness are but differing degrees of one and the same condition, involving, in the most serious all-comprising sense, obstructed education and inferior fitness for life-work; for whatever other good may be available, nothing can make up in the direction of effectiveness for the lack of that light—spiritual and physical—which comes by the eye alone.

If from any cause the eye receives impressions incorrectly, it necessarily transmits a faulty record to the brain, and the mind will as inevitably interpret on this erroneous basis. To such unconsciously falsified mental registry—due to purely mechanical variations in the reception of identical scenes or images in the eyes of different observers—may reasonably be attributed much of the inconsistency and discrepancy of human testimony and consequent miscarriage of justice, greater probably than has ever been estimated.

As the register of externalities, the eye determines the kind, quality, and result of mental as well as physical development, for although good sight will not insure a career of brilliant activity, nor bad sight positively doom its victim to seclusion and inefficiency, yet, other things being equal, the difference in the bearing upon character and capacity between good vision and poor vision is that of well-gauged impetus versus up-grade with brakes down—a difference calculated to bring originally identical abilities and ambitions, on the one hand, to vigorous, rounded develop-
ment; on the other, to warping limitations and abortive results.

The main eye trouble which has developed with civilization is myopia, or near-sightedness. It is the prevalence of this particular defect which urgently calls for remedial measures, even arbitrary ones, if necessary; for the common notion that the myopic eye will come out all right with patient waiting—"will be outgrown"—is a disastrous fallacy, exactly the reverse being true. Myopia, if attended to in childhood, may be modified, and in the greater number of cases may even be arrested in its further progress by the science of the lens, which restores the possessor of such eyes to a good place in the competition with those of normal vision.

As a rule, successful business men, clever lawyers, able politicians, shrewd buyers and sellers, possess accurate, normal vision; their visual perspicacity measures their mental perspicacity. Mental operations of a speculative or complicated nature depend mainly for their success upon the power of the eye to explore accurately the largest and most important field of investigation in the world, the one affecting directly and more variously the purpose and the performance of life—the human face and mind. To normal vision, backed by mental force and acuity and spiritual insight, the facial expression and gestures of our fellow-beings may be likened to a marvelous chart whose signal code of attraction and repulsion, offense and defense, courage and fear, doubt and hope, heroism and selfishness, sincerity and deceit, affords a beautifully intelligible and infallible guide to a wise conduct of one's own affairs and to a wise recession from or co-operation in the affairs of others.

This chart is a blank to the myope; the profound effect upon the character and faculties, the whole rich moral and spiritual results of its study, must be left out of the count in his development. In the struggles which maturity brings to most of us, those whose vision is defective must go to the wall, and especially the myope is likely to be forced to abandon, either at the start or in the hour of fulfilment, the chosen pursuit for which he has expressly fitted himself.

A few years ago a gentleman came into my office to seek my advice about his eyes. He had acquired reputation and independence by first-rate quality of clerical work, which he now suddenly found a difficulty in pursuing. Examination showed malignant—in e., rapidly increasing, with degenerative changes—myopia, with blindness threatened. I was obliged to advise immediate and permanent abandonment of the calling he loved, and that on the threshold of his success in it, and prescribed an out-of-door life, cutting off the need of using his eyes at short range, necessitating a degree of mental inactivity alien to his temperament and ambitions. All this disaster and disappointment could have been prevented, or at least very much checked, if the trouble had been discovered in his childhood and corrected with glasses, and he had been kept from too close application first in school and afterward in clerical work. He could then at that early date have readily adapted himself to the circumstances and pressed forward in some other direction. He received the sentence I found it so painful to give with really heroic resignation, for which his rare good fortune in getting the supervision of gold mines somewhere in Honduras seem like a merited reward.
In its effect on character, to see much and to see well, or to see little and that indistinctly, makes all or very much of the difference between the easily duped egotist, who is such because his visual world is so contracted, and the philanthropist, who is such because he sees the whole drama of life sufficiently well to estimate rationally and nobly his own part in it. It may fairly be said that we draw our character in part out of the well of universal personality, and the myope lacks the bucket for this well.

Now, nearsightedness is not only a question of disadvantage and limitation, it is a matter of great danger: it tends, uncorrected, not only to an impairment of the function, but also to loss of the power of visual acuity; its increase is accomplished by pathological changes and may at any moment culminate in detachment of the retina, which involves partial or total blindness, rarely, if ever, curable.

No one not himself an oculist can properly judge of the condition of his own eyes. This is particularly true of one who has never seen well, as there has been no previous better seeing to enlighten him. Myopia, hypermetropia (far sight), astigmatism (irregular sight), and abnormal binocular relations may, any one of these, be present in a greater or lesser degree unknown to the sufferer so long as pain or blindness do not manifest themselves. Often when I walk a few blocks or enter a car I see eyes more or less in need of the oculist’s attention, and in many instances the need is imminent if the eyes are to be helped, and yet the owners seem to be, and I think generally are, unaware of what is before them. We are not yet authorized, except in instances of immediate mortal risk, to save people without their permission, and though personal liberty is not without its sanctity, it does seem really pitiful to be obliged to act in the unsmarian manner and pass by on the other side. Even our patients, coming to obtain our advice, passing their own judgment thereon, do often discredit our warnings, partly from a notion that the oculist is overstating things which lie in his line, and partly from egotism and a determination not to believe.

If the inecalculable value of normal vision is realized, so will be the gravity of the situation embodied in the scientific dicta that normal vision is uncommon, and that with children (especially school children), the potential parents of the race, defective vision, and especially myopia, or tendency to myopia, is so general as to be almost the rule.

The nearsighted child is generally at the disadvantage from the start of not being known to be myopic; the child therefore suffers in feeling and in character from the perverting effects of dissymmetry and misjudgments; the instinctive diffluence and bashfulness born of uncertainty are misunderstood as obstinacy and unsociability. I can easily recall instances where bright little fellows who were unfortunately myopic were jeered at by their schoolmates and chided by their teachers for not reading sums readily or correctly from the blackboard, when the secret was they actually could not see distinctly. The others could see clearly, and the failures of the former were attributed to obstinacy or untruthfulness. In several of these instances I have had a personal part both as a youthful companion and later as a medical adviser, and therefore know whereof I speak.

In childhood the eyes should be watched, and the tendency to myopia or other defect be promptly and skillfully attended to. As a matter of course, we have long been accustomed to taking our children in inspection to the dentist; it would be of much greater result were we in the habit of periodically inquiring into the status of our children’s eyes. This threatening mischief—at least in its increased prevalence—can undoubtedly be traced in a great degree to the changes in our modern systems of education. In my own school days the hours of school covered the whole business of it; within them we learned and recited our lessons and then rushed out to care-free frolic. To-day school sessions are nearly or wholly absorbed in recitations only; thereafter the pupils are to be seen lugging home their text-books for evening and morning work at the cost of the play and rest, the entire change so necessary to healthy growth. And I am doubtful whether the degree of education afforded by the methods of to-day surpasses by virtue of this plan that of a generation ago. If it does, what avails it if we have suffered enduring physical loss thereby?

The entrance upon school life in the case of children showing either inherited or acquired near sight should be postponed, and they should be taught, as far as possible, textually, by the ear rather than by the eye, and outdoor life and sports requiring accurate distant vision should be encouraged. This course will insure results highly satisfactory. Certain plain, simple, general rules for the use and care of the eyes should be taught in schools and emphasized by the teacher’s watchful interest in their observance, such as that there should be neither study nor reading except by a good light (daylight failing, a steady oil light serves next best) falling over the left shoulder, brightening the page while leaving the eye itself in comparative shadow; no reading in cars or other vehicles (note the universal violation of this rule); that the sense of strain or fatigue should be immediately regarded by submitting to rest or change of work. Growing children should, as a rule, do no evening studying; what they might lose at the time of book knowledge will be immeasurably more than made good to them in the added store of health.

In the matter of selecting correct glasses I wish to strongly emphasize that it is the province of the oculist, not of the optician. The latter is rarely scientifically qualified, or if he were, could only continue to be so by a study and practice which would leave him no time as an oculist. It is the business of the oculist to prepare and fit the glasses specified in the oculist’s prescription. We should not think for a moment of passing by the physician and calling in the druggist to attend a child in scarlet fever, for instance: yet precisely this course is often followed in the case of defective vision, and almost every oculist sees daily the mischiefs done by acting on the well-meant but irresponsible advice of the optician. So well is this becoming recognized to-day that an oculist of repute will very seldom undertake to fit glasses except by the prescription of the oculist.
I hope it will not seem narrowly professional in me to reaffirm, in behalf of the children, that everything depends upon vision and upon caring for it in time. The scope of vision is the range of our whole possibility of aspiration and delight; it covers in all directions utility and livelihood, the ideal, art, beauty, in whose inspirations all latent gifts are quickened. What can hearing, or touch, or smell do in the search for new planets or deep-sea pearls? The astronomer, the analyst, the geologist, the botanist, the physiologist, the artist, the sculptor, the explorer, the chemist, the machinist—these and all their kind are Nature’s great interpreters by the light of the eye. And from all these, and kindred fields of highest service and distinction, defective vision shuts out its howsoever gifted victims.

I speak with a depth of feeling and conviction that will be quickly and sympathetically comprehended when I say that I speak as the burnt child. My own small craft in life’s great fleet was very near to being wrecked on the hidden reef of myopia! I shrank instinctively where my playmates rushed in; they saw clearly where to me all was indistinct in range and blurred in detail. I was unconscious of the defective vision and so were my companions, who misjudged and in many instances imposed upon me, for the myope is not a close observer.

Close attention to my studies increased the myopic condition. The skill of the oculist first gave me sight after a childhood passed in the dusk. For weeks after the first use of the correcting lenses I was occupied, almost to the exclusion of all other interests, with the miracle of the world I had never seen! Leaves, grass, the forms and plumage of birds, the shapes, colors, and movements of animals and all sorts of living creatures, the common things of daily use, the distant hills, the sky with its clouds by day and its stars at night, were all revelations, dazzling, delightful, engrossing; but most of all was I astonished and charged to the mind’s brim with a jostling rush of un-speakable reflections and provisions as for the first time I saw distinctly the features of the human face with their wonderful play of thought and emotion—an experience of both gain and loss, only to be adequately gaged by one who has passed through it. And the more impressive will this appear when it is remembered that mine was a case in exception to the rule, for usually after a long period of no correction myopic eyes can never be made to see normally, and are, moreover, in the ever-threatening danger of losing what little vision they yet retain.

To further emphasize and illustrate the necessity of caring for the eyes in childhood, I will cite a very interesting and complicated case which came under my observation. The trouble was astigmatism, about which we hear so much nowadays. The patient was forty-four years old. At the age of thirty he had been in active business life for some years, and began to perceive that he did not see as well as others and that it troubled him to work. He was successful and persisted until it was unendurable, then gave up work and traveled. He had put himself in charge of specialists, one of whom was a neurologist. He also visited an optician. By the latter a fatal mistake was unwittingly made in giving him certain glasses which required excessive exercise of the focusing (ciliary) power, thus aggravating the symptoms. Now, because of the fact that these glasses, by forcing his eyes to constantly overfocus, enabled him to see distinctly, the other fact, that this constant focusing steadily increased the original difficulties, escaped detection. Fourteen years later, when he had been pushed to the verge of insanity and to suicidal impulses, he happened to consult an oculist, and, thanks to the great general and special advance in ophthalmology during that period, it was possible after a long course of patient maneuvering to induce the ciliary muscles to relax and the eyes to accept proper glasses; since when he has been to some extent able to resume business, though inevitably under restrictions owing to the effect of so many years of ocular mal-habit. All this could have been averted by early attention in childhood.

My chief object in this paper is to show good convincing reason why it is the duty of citizens and parents to demand that the eyes of our children throughout the period of school life shall regularly receive skilled examination with a view to secure to them by protected and corrected vision the best possible conditions for development of character, and, as a consequence, the right selection of occupation with fair prospects of success.

Citizens and parents in the legislatures ought to frame and pass bills securing this benefit to our children, if citizens and parents out of legislatures ought to ask for these measures. It is a plan requiring to be founded upon authority, secure above the fluctuations of ignorance, impulse, or sloth. In my boyhood I used upon occasion to hear my grandfather say, speaking not profanely but profoundly, “Ignorance is the devil!” and of course the welfare of children should not be left to it, for the devil contests every step of the way with progress.

Examinations could be conducted by boards of health in co-operation with boards of education, as is now the case in the matter of vaccination. Records of these examinations, for subsequent reference and comparison, should be carefully made and filed, and certificates of details and advice could be issued to parents and teachers, which could not but assist them to more intelligently direct and control the development of children. Parents might do good supplemental service by securing additional examinations through their private medical advisers, and the certificates of the latter might serve in place of or additional to the legal or public examinations. If parents in some instances might not appreciate the serious importance of this plan, it seems reasonable to believe that in many others they would; and, as in all innovations, obstacles and prejudices so besetting at first would yield to time and the force of the accumulating proofs of both the necessity and the wisdom of such a measure. Those who, fortunately possessing sound vision and constitution, might derive no positive benefit, would at all events receive no injury, while the happy results for the many would more than justify the plan. Recall for a moment the case of the man self-exiled in Honduras. Had he when a child been living under laws requiring early and adequate examination of his
eyes, he would, ten chances to one, have been following successfully now his chosen avocation with that sense of efficiency and security so cheering in its effects upon the disposition and temperament, and so broadening and enabling to the character.

As a means of presenting this plan tentatively and practically, I would suggest what might be termed "Fund Examinations," in which a school or community by a trilling personal subscription raises a sufficient sum to secure the services of men competent to conduct these examinations and advise thereon. Under the practical working of such a scheme we should, I am convinced, far better comprehend the nature and tendencies of our offspring and often discover in hitherto puzzling peculiarities the exact adaptabilities for special paths in life. Much of the underlying latent unknown will become manifest. The universal auxious quandary of parents expressed in the too familiar phrase, "What shall we do with the child?" will be solved in the best way through the child itself, and with the splendid outcome of a very great diminution in the number of failures and in a vast increase in the successes of life!

The State is made up of units. The units are the people. Of these are you and I. A duty, inherent in our citizenship, demands that, in our allegiance to the State, we shall protect every individual unit; and, conversely, the State owes this duty to its component parts, to you and to me and to every one.

It is four years since I first advocated legislation in this direction. Shall four years again elapse before a decisive move is made?

GLIO-SARCOMA INVOLVING BOTH OPTIC THALAMI.*

By CHARLES E. NAMMACK, M.D.,
visiting physician, gourouier hospital, new york.

Abraham K., aged twenty-three years, Russian, furrier, was brought in an ambulance November 3, 1894, in a condition of profound coma. Of his family or his previous history nothing could be learned from his shopmates, except that for three days previously he had complained of headache and diarrhea.

Examination.—Patient pale and emaciated. Tongue dry, brown, and fissured. Pupils symmetrically contracted. Eyeball on the right side slightly protruded. Evidence of recent blistersing on the nape of the neck. Moist râles in the lungs. No cardiac murmur. Urine drawn by catheter showed a trace of albumin. Paralysis of motion on the right side. Sensation preserved on that side, as shown by efforts made with the left hand to remove irritation caused by the pricking of a pin. Temperature on admission 100°-4 per rectum, ten hours later rose to 104°, and thereafter fluctuated irregularly until death occurred six days after admission. Pulse on admission 90, and steadily increased until it reached 160, in the last thirty hours of life. Respiration ranged from 26 to 56. These latter changes were coincident with the development and progress of a pneumonia of the right lung. The case presented many of the features of another observed in the hospital a year before, and reported in the Medical Record of December 2, 1893, in which autopsy had shown extensive hemorrhage due to periplicate aneurysms in a young man of twenty-two. It was thought that the same pathological condition was present in this patient. The brain was therefore sent to the pathological laboratory of the New York Hospital, and the writer is indebted to Dr. George P. Biggs for the following report:

"The brain is inclosed in its dura mater, and has been in weak alcohol a short time. The dura and pia appear normal. There is very slight flattening of the convolutions of both hemispheres and marked bulging of the floor of the interpeduncular space. The lateral ventricles are greatly dilated, contain serous fluid, and measure when freely laid open eleven centimetres and a half in length and five centimetres and a half in width. The ependyema of the outer portion of the floor of each lateral ventricle is opaque. Upon removing the corpus callosum and forni a soft, smooth, grayish tumor is found, completely filling the third ventricle and the aqueduct of Sylvius, and blending with the optic thalami on each side so as to form a bridge between them on a level with their superior surfaces. The tumor lies beneath the velum interpositum, and is attached to it only over a small area, one centimetre in diameter, near its center. At the point of attachment the velum is a little thickened, but is elsewhere perfectly normal in appearance. Aside from the velum, the tumor has connections only with the upper half of the inner surface of each optic thalamus and there is not the slightest difference in the extent or completeness of the union on the two sides."

"The tumor measures six centimetres antero-posteriorly, three centimetres transversely, and two centimetres vertically.

"The left gyrus forniciatus, at a point near the posterior termination of the corpus callosum, is a little firmer than the surrounding tissue, and contains a few punctate hemorrhages.

"Sections of the tumor in the third ventricle show it to be a very vascular glio-sarcoma, the cells of which are mainly round or oval and of medium size. Granular intercellular substance is fairly abundant, but very few distinct gliomatous cells can be seen. Some of the blood channels have distinct walls, but most of them are simple canals in the tumor tissue. The velum interpositum at the site of its attachment to the tumor is infiltrated with cells of the same character as those forming the tumor. The hardened area in the left gyrus forniciatus presents hemorrhages of considerable size and great thickening of its capillary vessels due to development in them of cells like those of the tumor. A few such cells are also found in the pia over this area.

"It is impossible to determine the seat of primary development of this tumor. Judging from the extent of attachment, it would seem quite possible that the process might have commenced in both optic thalami, and the tumors later united in the median line; or it might have started in the velum interpositum. Development from the walls of the capillary vessels is clearly shown by a study of the more recent tumor in the gyrus forniciatus."

29 East Twenty-fourth Street.

The Society of Alumni of Bellevue Hospital held its fourth reunion in the form of a dinner at the Hotel Brunswick on Tuesday evening, the 12th inst. The president, Dr. Charles Clifford Barrows, acted as toast-master. There was a large company, and the speeches were highly entertaining.

* Specimen presented before the New York Neurological Society, December 4, 1894.
A CASE OF TUBERCULOSIS OF THE PHARYNX.

By E. HARRISON GRIFFIN, M. D.,
LECTURER ON DISEASES OF THE THROAT AND NOSE
AT BELLEVUE HOSPITAL MEDICAL COLLEGE;
ATTENDING SURGEON FOR THE THROAT AND NOSE,
OUTDOOR DEPARTMENT OF BELLEVUE HOSPITAL, NEW YORK.

An interesting case of tuberculosis of the pharynx came under my observation during the past year—interesting because the family history was unique, the diagnosis at first rather obscure, and the ability of the patient with a high temperature to attend to her affairs.

These cases are very uncommon. Willigk, in 1,317 autopsies of tuberculous cases, found the larynx affected in 297 cases, while the pharynx was affected in but one case.

A girl, aged nineteen years, came under my direct care in April, 1894, complaining of a slight increase of mucus which she hawked out of her throat in the morning. No cough was present at this stage.

An examination of her larynx was negative—no inflammation, no congestion. The pharynx showed a slight congestion, with here and there grayish-white spots scattered over the membrane.

I showed the case at this stage as one that portrayed tuberculosis of the pharynx.

The patient had no cough, did not feel sick, and was in fair physical condition. Her appetite was good and her sleep excellent.

The family history of this patient was unique: Her grandfather was alive, aged seventy-five years; her grandmother alive, aged eighty years; her father alive; her mother had died of typhoid fever at thirty-two years of age; no history of consumption in the family.

An examination of her lungs was negative. I made several examinations at this period and found nothing pointing to any lung disease. She denied any night sweats, but would have a light chill in the morning about nine o'clock; at twelve a fever would occur, and reach its highest point about half-past three in the afternoon. The fever at no time embarrassed her beyond making her thirsty and desirous of drink.

One day at the clinic I put the question to her: "Have you any fever to-day?" "No, doctor." The temperature taken by her mouth registered 99° F.; she came to the clinic unattended, and told me she would not know she was sick unless I told her.

An examination of the sputum showed the tuberele bacillus in large numbers. An examination of the lungs was negative, showing primary infection of the pharynx.

For weeks she had this high temperature in the afternoon; toward evening it would disappear, and at night she did not feel thirsty—her method of telling the absence of fever.

The case made rapid progress toward dissolution.

The small grayish spots in the pharynx extended, broke down into ulceration, and coalesced. Pain became a factor in deglutition and a cough made its appearance; the lungs were not recognizably involved till a month after the pharyngeal infection.

Death took place in August. I found that creosote internally administered relieved the fever quicker and more permanently than any other medication.

The family history, the high fever, and the ability of the patient to come and go four miles for treatment with this high fever, rendered this case very instructive and interesting.

The quick time of dissolution conforms to the usual history of these cases: the nearer the air the tuberele bacillus is ingrafted, the quicker the death of the patient—generally within four months after the primary inoculation.

I have treated one case of laryngeal phthisis where the disease ran two years before the patient succumbed. Pharyngeal phthisis kills generally in from three to four months.

SEPTICÆMIA

FOLLOWING CONFINEMENT OR MISCARRIAGE.

A TREATMENT BELIEVED TO BE NEW.

By D. ROSE, M. D.,
CHICAGO.

For the last three years or more I have been taking a course in the above-named cases that is original with myself, and one which I have now tested in a sufficient number of cases to justify me in recommending it to the profession in general.

There is no doubt that many women have lost their lives from septicæmia, and I frequently hear of such cases still; but I venture the assertion that no case need result fatally from that cause if the following easy treatment is promptly and properly carried out.

If the above-given assertion be true, it is the duty of every physician taking such cases under his care to be influenced by another's experience.

As soon as any symptoms show themselves I bring the lips to the edge of the bed, introduce a bivalve speculum, and, with borated cotton in a Bozeman's long dressing forceps, wipe out thoroughly the whole uterine cavity until the cotton comes away odorless and clean. I then dip a bunch of the cotton in iodized phenol and dab it over the whole interior of the uterus.

It has never caused pain or the slightest unpleasant symptoms of any kind, and from the first treatment (and one is often sufficient) I have never seen the symptoms increase. In a few hours the change for the better is surprising, and the rapidity with which involution takes place is simply marvelous.

I give internal remedies as indicated, and repeat the treatment next day, and every day in cases requiring it, until the indications cease.

Cotton will wipe away shreds which the intra-uterine douche leaves behind. There is no danger of fluid passing through the Fallopian tubes. You can tell when the uterus is cleansed and the exact odor and appearance of what you get away, which you can not do when using water.

The application of iodized phenol has all the advantages of that of mercury bichloride, and the rapid involution which follows its application can not be realized until it is seen.

Lacerations of the cervix are never left with thick, poultising lips and callous edges, and it will save from the necessity of many operations for the repair of old lacerations.
THE IMPROVEMENT OF PHARMACOPEIAS.

The British Pharmacopoeia, the last edition of which appeared in the year 1885, is soon to undergo another revision under the direction of the General Medical Council. In view of this fact the British Medical Journal announces its intention of publishing a number of articles calculated to bring out the deficiencies of the present Pharmacopoeia and to point out in what directions it can be improved. The first of these articles, dealing with the subject from the prescriber's point of view, is by Dr. T. Lauder Brunton, and it appears in the issue of February 2d. Dr. Brunton occupies most of his space with discussing the question of why it is that the Pharmacopoeia itself is in the hands of so few medical men, while almost all of them possess Squire's Companion to the Pharmacopoeia or Martindale and Westcott's Extra Pharmacopoeia. He finds the answer in the fact that the Pharmacopoeia gives a great deal that the practising physician does not care to read and has no occasion to read, while it is lacking as to many things that he does wish to know about and which are given in the two other works mentioned. He goes on to say that it is not the physician only that finds himself in this position, but the dispensing apothecaries also, who do not, as a rule, make their own preparations, but buy them from large manufacturing firms. As to both these points, the profession of medicine and that of pharmacy stand in much the same relation to the British Pharmacopoeia as they stand in this country to the United States Pharmacopoeia, and it is well known that apothecaries depend far more upon the dispensatories than upon official pharmacopoeias. There is much force in what Dr. Brunton says on this point, but in our opinion it would not do for full directions for the preparation of pharmaceutical products to be omitted from a pharmacopoeia, for, if they were, there could hardly be any practicable way of requiring that such preparations made by manufacturing pharmacists should conform to a definite standard, and such conformity is unquestionably most desirable.

Among the other suggestions made by Dr. Brunton is that of the usefulness of having stated in a pharmacopoeia not only the individual doses of pharmaceutical preparations and crude drugs, but also the total amounts, regardless of individual doses, that may properly be administered in the course of twenty-four hours. Still further points on which he comments relate to the desirability of directions for making extemporaneous mixtures agreeable to the palate; to directions for the preservation of perishable drugs; to the desirability of reducing the size of the official pills, which patients often say they can not swallow; to recognizing such preparations as cachets and capsules; and to the addition of extensive tables of solubilities, together with statements as to how much of a drug that has been dissolved in a liquid with the aid of heat remains undissolved in the liquid after it has become cold.

In some respects, according to Dr. Brunton, even the directions for making preparations are quite inadequate and decidedly wrong in the case of some of the preparations given in the British Pharmacopoeia. For example, under the head of casta plasma conii, he says, we find that an ounce of hemlock juice is to be evaporated to half its volume and then mixed with half a pint of boiling water and a quarter of a pound of linseed meal. He says that he has never made this poultice himself, and that he knows of nobody who ever has made it, but if it ever has been made, he would like to know who evaporated the hemlock juice and made the poultice, because, he says, if the apothecary evaporated the juice and made the poultice it would be cold before the patient got it, while if the juice was evaporated at the patient's home there would probably be no proper dish in which to evaporate it. He adds that any ordinary person would simply use a little less boiling water and a little more linseed meal and leave the hemlock juice without evaporation.

THE DOCTORS OF THE NATIONAL GUARD OF THE STATE OF NEW YORK.

Last week we spoke in commendation of the conduct of the medical members (officers and privates) of the militia while they were on duty recently in Brooklyn. We knew at the time that the field and line officers of the regiments engaged appreciated the character of the medical men in their commands, and we have since been favored with weighty additional testimony to that effect. From an officer of one of the regiments we have received a letter—indeed, it reached us before last week's issue was off the press—in which he says that it seems to him that at this time it is very appropriate to have some mention made in the medical journals of the medical officers of the National Guard. He does not think that the general public is aware of the sacrifices they have to make—unless it may be their patients whom they have to neglect during their absence. He says that in his experience he has found the surgeons particularly attentive, not only to their medical duties, but also to their military duties. They are always, he testifies, exceedingly faithful, and their moral support to the commanding officer is much greater than is supposed. There is no member of the staff, he adds, to whom the commanding officer can so readily appeal as to his surgeon. The surgeons help him in the discipline of his command, and of course in the sanitary and commissary departments they are invaluable. Every article of food is passed upon by the surgeons, the cleanliness of the posts comes under their observing eyes, and they share with the rest of the command every danger.

"I would particularly," says the officer, "draw your attention to the professional conduct of Dr. Colles, our second assistant surgeon, who, on that foggy Monday afternoon when the First Battalion was assailed on all sides by missiles of every description,
and two or three of the men were severely wounded, bound up in the most scientific and prompt manner the wounds of these men while the command was halted and drawn up in a square to receive any further attacks, a missile of some kind coming within close quarters of him every moment. Not a word was spoken in the square, there was absolute silence, and you can imagine what a dramatic scene it was. One man was carried along on a stretcher by the Hospital Corps, the hospital steward in close attention."

Of course, adds the officer, this is a mere matter of duty that may not strike one as being very much out of the common, and it is more in the direction of the great sacrifices the surgeons make which it seems to him should be noticed in medical journals. While everybody has to make sacrifices, he continues, the surgeons contribute doubly to the benefit of a command, because they give from their professional knowledge in addition to what they lose in the way of practice. He closes with an expression of his hope that we can be as enthusiastic over the doctors as he is.

Another commanding officer, Colonel Greene, of the Seventy-first Regiment, writes to us in praise of the medical officers on his staff. The surgeon, Major Marsh, he says, is "one of the most efficient and accomplished surgeons in the military service—either Army or National Guard," and he particularly commends Dr. Marsh's devices in the way of a portable chest containing medicines and appliances for use in either the armory or the field, and in the way of stretchers. Colonel Greene says that they are "generally conceded to be the best in the service, and were very much admired by professional visitors in Brooklyn." This interested us so much that we have since taken advantage of Colonel Greene's courteous invitation to us to inspect the appliances referred to and of Dr. Marsh's cordial offer to demonstrate and explain them. They are indeed excellent, and they are the result of Dr. Marsh's own ingenuity and generosity, for we understand that they have been provided at his own expense—indeed, much of the work of preparing them was done with his own hands. So far as it goes, the provision made by the State as regards such matters is very good, but it ought to go further; we think the State should see to it that every regiment is provided with a similar outfit. Moreover, each regiment ought to have at least four field cases of instruments, instead of only two, as at present. The National Guard can not be too well taken care of.

MINOR PARAGRAPHS.

HONORS TO BRITISH PHYSICIANS.

The Practitioner, which changed its editor and publishers at the beginning of the year, is but little altered in its general appearance. One novel feature in it, however, is calculated to excite attention and interest; we allude to a number of pages of short editorial paragraphs, each without a title of its own, but all grouped under the general heading of The Month. They are written in the first person singular, and probably by the editor, Mr. Malcolm Morris. They are very crisp and readable. One of them, published in the February number, reads as follows: "The New Year's honors, if, as usual, somewhat meager as far as our profession is concerned, have last year been thoroughly well bestowed. There are no two men more worthy of such honor as the sovereign can give than Sir Russell Reynolds and Sir John Eriksen, and there are none whose selection for the distinction could have been more fully ratified by the judgment of their profession. For my part, I can not help feeling that the distinction should in each case have been conferred long before; it is satisfactory, however, that it has come at last. The Crown might, indeed, find some better way of doing honor to those to whom honor is due in the medical profession than the bestowal of titles which are often flung to fill the number of an importunate party back, or given in payment for that kind of political support which takes the form of checks. Peerages are open to the same objections, and there is something incongruous to my mind in the idea that men whose work has been the relief of suffering and the betterment of human life should be rewarded in the way that is deemed most appropriate for successful cultivators of the art of scientific slaughter and manufacturers of the materials of intemperance. Why should not distinguished members of the medical profession be sworn of the Privy Council? The Privy Council itself would be greatly strengthened by the infusion of a new element representing that profession which, according to Mr. Gladstone, is at no distant time to be the greatest power in the State. There is a special fitness in such a distinction for men whose training and experience must make their advice on matters relating to public health of particular value, and it is a curious anomaly that the Crown has hitherto had no medical men among its councillors. Professor Huxley is only an apparent exception, for the honor in his case was conferred in recognition of his scientific eminence and his services in various public capacities."

DOCTORS AS EXECUTIONERS.

The following letter of inquiry was printed in last Sunday's Sun: "If a man is sentenced to death by the electric chair, and after the current is applied and the doctor in attendance pronounces him dead his friends revive him through this new method or any other, does he gain his liberty, or must he serve the rest of his life in prison?" The Sun's answer was as follows: "The execution under the present law in this State isn't completed until the doctors have performed an autopsy. In other words, the doctors are executioners. After they have cut the criminal up there is no doubt about his being dead." This has an ugly sound, but who can demonstrate that the Sun is wrong?

SECOND-HAND MEDICAL BOOKS.

The publishers of this Journal, Messrs. D. Appleton & Co., having learned that one J. S. Dunbar, a canvasser for the sale of medical works in the State of New York, has offered and is still offering to supply physicians with any of their subscription books at reduced rates, request us to state that neither the individual named nor any other person can purchase new books of that class at any reduction from the advertised price. It follows, therefore, that books so offered for sale must be second-hand and have been obtained from the original purchasers either by exchange for other books or by purchase at second-hand rates.

MEDICAL FREEMASONS IN NEW YORK.

Arriving of a leading article in last week's Journal, on Medical Freemasons in Great Britain, we learn from a lay
friend that in Kane Lodge, of New York, there are perhaps more medical brothers than in Aesculapius Lodge, of London. This seems eminently appropriate as the lodge was named in honor of Dr. Elisha Kent Kane, of the United States Navy, the arctic explorer, and its membership, which includes some of the most prominent men in clerical, legal, scientific, financial, and commercial circles, would be incomplete but for representatives of the medical profession whose names are known and honored wherever the English language is spoken. This is not surprising, for those that are Masons can easily recognize how the principles of Freemasonry would appeal to a medical man.

ITEMS, ETC.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending February 12, 1895:

The New York State Examination in Medicine.—The board of examiners, as is generally known, consists of three boards representing respectively the Medical Society of the State of New York (non-sectarian), the Homeopathic Medical Society, and the Eclectic Medical Society of the State of New York. The first-named board, of which Dr. William C. Wev, of Elmir, is president and Dr. Maurice J. Lewi secretary, has recently submitted to the Medical Society of the State of New York a report of its work for the year 1894.

It is remarked that the following statistics, given in the report, should not be confounded with those prepared by the regents' examination department, as their records are made up annually to conform to their general method of compilation, which is based on the opening and closing of the academic year, August 1st to July 31st:

The report says it was thought in 1891 that the average number of candidates who would yearly appear before the board for examination would be about 490. This estimate was based on the theory that the law admitting candidates to examinations was so stringent as to exclude all not well prepared to pass the tests. Candidates for admission must be of good moral character, as certified by two reputable practitioners of medicine; they must be graduated doctors of medicine who have attended at least three full courses of lectures at a registered medical school in three different years; and must have had the preliminary education prescribed by law. These exactions, it is remarked, tend to shut out the incompetent, and in consequence the percentage of rejections must be considered in this light. The discrepancy between the estimated and the actual number of candidates is imputed to two causes. Whereas, prior to 1891, the number of physicians who settled yearly in the State was from 700 to 800 (and this can only be estimated, as no exact figures are obtainable), now there are fewer than 400. The applicants numbered 536, as above stated. The natural increase in the population might account for a corresponding increase in the number of medical men; but the main cause is the fact that our State licenses have grown to documents of such importance that most of the States having boards of medical examiners accept them as licenses to practice without exacting added medical tests.

The selection of questions properly grouped for examination purposes, says the report, is a task to which much time has been devoted, and the board invites criticism of its work in this particular, with the hope of improving on a system which has been generally commended. The questions are originally framed by all the examiners, each chair, through its three representatives, submitting, as occasion requires, 160 questions. A total of 1,080 questions thus obtained is referred to the question committee, composed of two members from each board. By that committee the questions are carefully studied and sifted, only such being accepted as are considered fair, that is, as requiring knowledge which every practitioner of medicine should have. To the committee's editor are then referred all accepted questions, and he in turn groups them in sets of fifteen in each topic, covering as nearly as possible every sub-branch of the subject under consideration. On requisition of the regents, these groups are forwarded to Albany and the regents become responsible for printing and for the language used in framing the questions for publication. Thus far, twenty-one regular and three special examinations have been held, at which 2,520 questions have been asked, or 360 questions in each topic. A duplication of questions thus propounded and published to the world, says the report, is not desirable, but a point has now been reached where this is becoming essential if the board is to be freed from the charge of propounding queries which belong in the special fields of medicine rather than in its general field. Other similar bodies of examiners, it is remarked, submit and publish questions which indicate a far more difficult test for the license, but the method of marking seems to the board comparatively lenient as judged by the percentage of rejections. The board feels it to be its duty not to prevent a given percentage of those applying from being licensed, in order to maintain a standard, and prefers to act favorably on the application of all, no matter how great the number, whom it believes to be competent to practice medicine.

Under the provisions of the law it is permitted to indorse, as sufficient for practice, the licenses issued by other State boards of medical examiners, provided the standards of those bodies are not lower than ours. Numerous applications from various States have been received for this indorsement, but on investigation the board has in each instance found that the standard was not sufficiently high to warrant it in approving the documents submitted. The board earnestly appeals to the society to continue the work, inaugurated by the committee on legislation in 1892, of having bi-monthly transcripts of registration made from the books of the county clerks throughout the State. In this manner only, it says, can a comprehensive record of the registration throughout the State be secured, thus furnishing the opportunity of verifying or correcting the work of the county clerks. During the year many letters have been addressed to the board, calling attention to persons who are practicing medicine in various parts of the State without legal authority. It has been the board's custom to investigate all such cases and to advise prosecution where the offender is a new-
ITEMS.

WHEREAS, the same is substantially true of the condition and management of the institutions for the dependent insane of the county of Kings:
Resolved: That both the dictates of humanity and the interests of the taxpayers demand that the principle of State care for the dependent insane, which has proved so satisfactory in the fifty-eight other counties of the State, should speedily be extended to the counties of New York and Kings.

Resolved: That the committee on legislation be instructed to request the Legislature to adopt such measures during the present session as will secure the transfer of the dependent insane of the counties of New York and Kings to the control of the State.

The Academy of Medicine’s Section in Obstetrics.—Dr. Henry C. Coe has issued the following circular: “Having been recently elected chairman of the Obstetric Section of the Academy of Medicine, it is my earnest wish to revive the flagging interest in the meetings, as well as to improve the quality of the scientific work. I shall feel greatly obliged to you if you will aid me with your presence and influence, and will engage to read a paper or to take part in the discussions. Your views are far more likely to reach the general profession, who attend the meetings of the section, than is the case when they are expressed before a small audience of specialists.”

Change of Address.—Dr. D. Rose, to No. 1064 Milliard Avenue, Chicago.

Army Intelligence.—Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from February 3 to February 9, 1895:

ROBERTSON, REDWIN L., Captain and Assistant Surgeon. The extension of leave of absence granted is further extended fourteen days.

KENNEDY, JAMES M., First Lieutenant and Assistant Surgeon. The leave of absence granted on account of sickness is extended one month, on account of sickness.

Naval Intelligence.—Official List of Changes in the Medical Corps of the United States Navy for the week ending February 9, 1895:

BAGG, C. F., Assistant Surgeon. Detached from the U. S. Steamer Mohican and ordered to the Naval Hospital, Mare Island, California.

BRATHWAITE, F. G., Assistant Surgeon. Detached from the Naval Hospital, New York, and ordered to examination preliminary to promotion.

SROCOTTON, JAMES, Assistant Surgeon. Ordered to examination preliminary to promotion.

Society Meetings for the Coming Week:
MONDAY, February 18th: New York Academy of Medicine (Section in Ophthalmology and Otolgy); New York County Medical Association; Hartford, Conn., Medical Society; Chicago Medical Society.

TUESDAY, February 19th: New York Academy of Medicine (Section in General Medicine); New York Obstetrical Society (private); Oglethorpe, N. Y., Medical Association; Syracuse, N. Y., Academy of Medicine; Medical Societies of the Counties of Chenango (quarterly), Kings, Livingston (quarterly), and Westchester (White Plains), N. Y.; Baltimore Academy of Medicine.

WEDNESDAY, February 20th: Medico-legal Society, New York; Northwestern Medical and Surgical Society of New York (private); New Jersey Academy of Medicine (Newark).
To the Editor of the New York Medical Journal:

Sir: In the article of Dr. Emily Lewi on The Milk Supply of New York in your last issue (February 9, 1895) the author has treated my suggestion of filtering milk before sterilizing it in a manner so uncommon in scientific literature that I deem it my duty to call special attention to this innovation.

At the last meeting of the American Pediatric Society, in Washington (May, 1894), I reported on a method of cleansing milk by filtering through a thin layer of clean absorbent cotton, which process not alone removes the gross filth so often found therein (and in the sugar water), but also diminishes the bacteria in the milk to at least an eighth of their original number. About seventy experiments (of which fifty were of a bacteriological character), made in the course of six months by myself and by Dr. Kiliani, of this city, have demonstrated the feasibility of this plan of replacing the centrifugal machines of large milk establishments in the households of people of moderate means (Archives of Pediatrics, July, 1894).

This method, since practically established in artificial infant-feeding, Dr. Emily Lewi described in the following words: "The process of filtration to which attention has been somewhat directed of late, was employed. The Seibert aluminum filter, as of most recent date, was used."

This description naturally gives the impression that I had proposed to filter milk through a layer of aluminum (instead of absorbent cotton), all the more so as Dr. Emily Lewi, in the entire report of her critical experiments, carefully conceals the fact that absorbent cotton was used in this milk filtration by not even once mentioning the word cotton.

But this omission does not stand alone. In the discussion of her paper at the Academy of Medicine, Dr. Emily Lewi asserted that she had first sterilized the cotton discs used in her critical experiments, a statement which does not appear in the article itself, where it certainly ought to be, for it proves beyond all doubt that the increase of acid found in two of her three filtration tests was solely due to her unclean handling of the cotton. Increase of acid in milk means increase in the number of bacteria causing acid, and increase of bacteria in sterilized cotton means unclean handling after sterilization. Septic surgery and obstetrics have not yet entirely gone out of existence in this aseptic age, and we may now recognize the possibility of adding (instead of removing) dirt and bacteria to milk by filtering through unclean cotton. This discovery, in itself not surprising, has been scientifically demonstrated by two of the three experiments of Dr. Emily Lewi, and she ought to have the credit for it.

Three fourths of a column of your journal are devoted by Dr. Emily Lewi to "indicating the negative influence of filtration as delaying the souring of milk," yet she has seen fit to omit mentioning my only article published on this subject in the bibliography at the end of her paper. This necessarily prevents the unbiased reader from comparing the report of the numerous experiments made by Dr. Kiliani and myself with the three tests of Dr. Lewi, one of which speaks for and the remaining two speak against a possible value of cotton filtration of milk.

Among scientific men it is customary to make no such omissions as have been made in Dr. Emily Lewi's paper, because they prevent the clear understanding of the subject under discussion, and are not fair to the criticised and not creditable to the critic.

In conclusion, I will mention that the removal of gross filth from milk by centrifugal machines has for years been recognized by men like Soxhlet and Escherich as a correct procedure. Cotton filtration answers the same purpose, and keeps dirt not only out of the nursing-bottle, but also out of the alimentary canal of the infant, where, not being digestible, it is reinfected and can only do harm.

A. SEIBERT, M. D.

STRANGULATION OF THE PENIS.

To the Editor of the New York Medical Journal:

Sir: In your issue of December 8, 1894, you mention three cases of strangulation of the penis. I should like to place another case on record.

J. F. entered the Rhode Island Hospital on February 23, 1893, during the service of Dr. G. L. Collins, with gangrene of, apparently, the whole penis, and giving the following history: Six weeks before his entrance he had contracted gonorrhea, and, being much annoyed by the flow of pus, he had tied a string around his penis, thus stopping the flow of pus and incidentally the circulation of the blood.

The gangrenous portion soon separated, and the slough consisted of the whole of the skin of the penis and a small portion of the glans. He refused to be moved from the contagious ward into the regular surgical wards, and so left the hospital, refusing skin-grafting, and all trace of him was lost.

I might also mention the fact that at the same time he was under treatment we had in the hospital another unfortunate who had been the cause of his gonorrhea, who was undergoing treatment for burns received at a fire in a low resort of the city, and who was also being treated for delirium tremens.
LETTERS TO THE EDITOR.—PROCEEDINGS OF SOCIETIES.

Dr. Higgins, of this city, tells me he saw a case some time ago where superficial gangrene of the penis resulted from the constriction of a young man’s penis caused by a finger ring his mistress had placed upon it.  

JAY PERKINS, M. D.

A JOURNAL OF DIGESTIVE DISEASES.

Baltimore, February 12, 1895.

To the Editor of the New York Medical Journal:

Sir: The rise of a specialty in medicine is marked by the appearance of journals especially devoted to it. We are glad to inform you that the new specialty of diseases of the digestive organs is about to have its own publication, the Archiv für Verdauungskrankheiten, which will appear in April. It will be published in Berlin, Germany, by S. Karger. The editor is Dr. I. Boas, of Berlin, the well-known author of a work on Diseases of the Stomach. He will be assisted by specialists in Germany and other countries. The Archiv will contain original articles, besides reviews and abstracts of recent literature, and will embrace diseases of the stomach, intestine, liver, pancreas, and peritoneum, constitutional diseases, and dietetics. Those interested may communicate with the editor or the publisher.

JULIUS FREIDENWALD, M. D.

Proceedings of Societies.

MEDICAL SOCIETY OF THE STATE OF NEW YORK.

Eighty-ninth Annual Meeting, held in Albany, on Tuesday, Wednesday, and Thursday, February 5, 6, and 7, 1895.

The President, Dr. GEORGE HENRY FOX, of New York, in the Chair.

A Few Practical Points in the Diagnosis and Treatment of Pelvic Hematocele.—Dr. W. E. COLEBROVE, of Horseheads, read a paper on this subject. The pathology of the condition was first referred to, and disease or injury of the pelvic vessels was given as the efficient cause. The condition might be either intraperitoneal or subperitoneal, and the quantity of blood effused varied from a small quantity to one which would be immediately dangerous to life or even fatal. It was safe to say that such an effusion of blood in any considerable quantity was always dangerous. A case was then narrated which had been erroneously diagnosed as one of acute retroflexion of the uterus, but which had proved, on closer examination, to be a hematocele that had become hardened after the absorption of the serum, simulating a uterine fibroid, and in which also decomposition with symptoms of sepsis had already taken place. The tumor had been treated by vaginal incision, irrigation, and drainage, and the case had resulted in recovery. It was remarked in conclusion, that in supposed cases of retroflexion of the uterus pressure by means of vaginal tampons should not be used until it was quite clear that retroflexion was actually present.

The Use of Chlorine in the Treatment of Typhoid Fever was the title of a paper read by Dr. R. W. WILCOX, of New York. Chlorine had been used as a disinfectant from the time of Haller. It was not so irritating to the alimentary canal as was usually supposed. It was absorbed by all the tissues of the body when inhaled or taken in solution by the mouth, and produced its characteristic staining. If given in small doses in properly diluted solution, it would increase the secretions and facilitate digestion. It was a stimulant to the liver and kidneys, and combined most readily with oxygen. It helped dispose of the toxins which were present in typhoid fever, was a stimulant to the heart, and was a rational means for the disinfection of the ulcerative lesions which obtained with typhoid fever. It could be given in doses of from one to four fluidrachms in a very dilute solution prepared by the combination of potassium chlorate with hydrochloric acid, or by means of the official solution of chlorine. It was worthy of a trial in cases in which other medication had been ineffectual, and its use could be continued until complete disinfection, as shown by the discharges, had been accomplished.

The Care of the Ears during the Exanthemata was the title of a paper by Dr. W. C. PHILLIPS, of New York. Many cases of aural disease developed in connection with scarlet fever and measles, and in most of them recovery resulted. There was inflammation of the entire mcosa of the auditory apparatus, involving also that of the Eustachian tubes. The dorsal deciduous which was usually assumed by the patient favored the accumulation of the morbid secretions, and the latter must be removed as thoroughly as possible. The child’s nose should be blown frequently to assist in dislodging the secretions, and applications should be made of boric acid, glycerin, peroxide of hydrogen, etc. The great object should be the prevention of extension of the inflammation to the structures of the middle ear.

Dr. J. E. II. NICHOLS, of New York, suggested that the diseased surface should be anastomosed with cocaine before treatment was instituted, to enable one to treat the condition with greater thoroughness. Children were often refractory to such manipulations. The blowing of the nose which had been suggested should not be too violent, and only one side should be blown at a time. This precaution was often a very necessary one.

Tubular Cork Splints for Deformities of the Nasal Septum was the title of a paper by Dr. T. P. BERNES, of New York. The method of operation upon the nasal septum which had been so much in vogue were, he said, in very many cases not productive of good results. The method now proposed was simple, and ordinary bottle corks could be prepared by the physician at a moment’s notice. They should be shaped to fit the nasal cavity with accuracy, and then could be covered with collodion to prevent irritation. If a deformed septum was to be treated, the nasal bones should first be carefully fractured and the fragments placed in proper apposition to each other. The splints were then to be inserted into one or both cavities, according to the sensitiveness of the parts. They might be kept in situ for a week, or they could be changed in twenty-four hours if they caused pain. It was better to leave them in position one or two weeks if they could be worn without too much discomfort.

The Dry Treatment of Otitis Media Suppurativa was the title of a paper by Dr. J. E. II. NICHOLS, of New York. He said the treatment did not consist merely in the insufflation of boric acid, which resulted mainly in shutting in the secretions and the formation of a hard plug; indeed, such a treatment was not curative and would usually cause desquamation of the skin of the external ear. He had arranged an ear kit for the treatment of such cases, a suitable syringe and a bottle of peroxide-of-hydrogen solution being essentials. The dry treatment advocated consisted in removing the secretions as soon as they were formed. The ears should be inspected at least twice a week until the bad symptoms were relieved. If the perforation in the tympanum was small it should be enlarged and free cleansing and drainage established. The curette should be used to remove any dead or decomposed tissue which might be present, and the use of a caustic of moderate strength should follow that of the curette, but only a minute quantity should be used.
The second case was one of typhoid ulcer of the larynx. There had been hemorrhage from the bowels during the second and third weeks of the disease, and great consequent emaciation; then there were symptoms of stenosis of the larynx with urgent dyspnea. Intubation had been tried three times unsuccessfully, and as a last resort tracheotomy had been performed rapidly and recovery had resulted, though the larynx appeared seriously crippled and it had thus far been necessary to leave the tracheal wound open.

(The to continued.)

THE NEW YORK NEUROLOGICAL SOCIETY.

Meeting of Tuesday, December 4, 1884.

The President, Dr. Edward D. Fisher, in the Chair.

Tumors of the Brain.—Dr. Charles E. Nammack gave the history of a case of brain tumor, and exhibited a post-mortem specimen showing the location of the growth, which was a spindle-celled sarcoma in the left frontal lobe. The full history of the case had been published in the Medical Record for May 12, 1884. He also reported another case (see page 208) and exhibited a specimen in connection therewith.

Two Cases of Cerebral Syphilis were presented by Dr. Nammack. The first patient was a man, aged thirty-four years, a cloth-examiner. He had contracted a chancre in October, 1889; six weeks later he had suddenly become unconscious and had no recollection of what had occurred during the succeeding forty days. Following this there had been hemiplegia of the right side, which had confined him to bed for three months. The patient had been put on specific treatment as soon as the initial lesion was discovered, and this had been continued vigorously until the fall of 1889. About six weeks after the treatment had been left off, the patient had been attacked with severe occipital headaches and bitemporal hemianopsia, with astasia and exaggeration of the knee-jerks. Under specific treatment, these symptoms had now almost entirely disappeared. Dr. Nammack said the lesion in this case had probably been a gumma situated in the substance of the optic chiasm.

The second patient presented was a man, aged forty-four years, who had complained of dizziness, bilateral occipital headache, tinnitus, absolute deafness of the left ear, and diplopia. He also had had the characteristic cerebellar gait. The history of syphilis in this case had been rather obscure, but under specific treatment the man's symptoms had almost entirely disappeared. The diagnosis in this case had been that of gumma in the cerebellar region.

Muscular Dystrophy.—Dr. B. Sachs showed a young woman with all the characteristic symptoms of muscular dystrophy of the facio-scapulo-humeral type. On attempting to show the teeth, she was able to retract the lower lip slightly, the upper one not at all. There was also a loss of power in the eyelids, and the conditions in the region of the shoulder girdle were very characteristic. There was distinct hyper trophy of the infraspinitus and supraspinatus, with atrophy or partial atrophy of the serratus, the pectorals, and the rhomboids. The patient was unable to raise her arm beyond a horizontal attitude. Dr. Sachs said that last July he had excised quite a large piece of the infraspinitus muscle, and in doing so a considerable part of the nerve as it entered the muscle had accidentally been removed. A histological examination of the specimen had shown a great preponderance of fatty tissue; some of the muscular fibers were hypertrophied, but most of them were atrophied; there was also distinct evidence of a marked degeneration of the nerve. In view of the discussion that was now being car-
ried on regarding muscular dystrophies, the fact that the nerve in this specimen had been found to be affected was of particular interest, although, of course, no decided inferences could be drawn from a single case. There had recently been a positive improvement in the condition of this patient. In the lower extremities there was slight atrophy of the muscles.

Rapid Glosis of the Spinal Cord.—Dr. L. E. HOTR and Dr. C. A. HERTER reported the case of a male child, aged one year, who had been admitted into the Babies' Hospital on February 21, 1894. His family history was good. His parents had two other children, who were healthy. Three months previous to his admission the child had been noticed to be weak in the right arm and hand, and at about the same time his head had begun to droop forward. The motor paralysis in the right arm had gradually increased, and finally there had been complete loss of power in both arms and in the shoulder muscles. The muscles in these regions had become decidedly atrophied and flabby in consistence. The muscles of the neck were exceedingly rigid, and the head was carried stiffly, slightly in advance of the normal position, with the face looking directly forward. There had seemed to be some loss of power in the legs. The knee-jerks were exaggerated, especially on the right side; ankle clonus was obtainable on either side. There was considerable dyspnea and coughing, which could be heard over the entire chest; there was no sign of consolidation. The child's temperature, on admission, was 102°; it showed irregular daily variations, ranging from 100° to 105° and even higher. There was occasional vomiting. The pupils were equal; they were normal in size and responded to light. There was partial analgesia of the body below the arms. The respirations ranged from 82 to 52 a minute. On March 16th slight strabismus was noticed, and the head was rolled continually from side to side. At times there was marked cyanosis. The temperature rose to 106° and the child died at 6 p.m.

At the autopsy, a grayish projecting mass was found, which occupied almost the entire right side of the medulla and a large part of the left side. The medulla was considerably enlarged from before backward and from side to side. There was also considerable enlargement of the cord, as far down as the eighth cervical segment, and from this point to the sixth dorsal there was some enlargement; below this the cord appeared to be normal. A histological examination of sections of the growth from different parts of the cord revealed a typical gliomatous structure which involved, to a greater or lesser extent, the medulla and almost the entire cord. Dr. Herter said the appearance of the preparations examined rendered it probable that the new formation of gliacells had been derived from the proliferation of the ependymal and periependymal cells. Although the new growth had involved almost the entire extent of the spinal cord, it was only to the well-developed growth in the upper half of the cord that the symptoms presented by the patient had been attributable. The high temperature could hardly be accounted for by the patient's pulmonary condition, and had probably been due to the rapid destruction of nerve elements in the spinal cord. In connection with the paper, Dr. Herter exhibited a number of photographs showing the microscopical appearance of the growth at various levels of the cord.

Tumor of the Lumbar Region of the Spinal Cord.—Dr. ISA VAX GIESON and the President reported the case of a man, aged sixty-one years, a German carpenter. He had been admitted into a hospital on April 18, 1894, when notes of the case had been taken by Dr. A. F. Witten, the house physician. His family history was negative. He had had syphilis at the age of twenty-five. There was no history of alcoholism. For about six months previous to his admission he had suffered from pronounced dizziness on standing erect. His memory was good. There was diplopia of three years' duration. His hearing was good, his speech was normal, and there were no gastric symptoms. During the preceding eight months he had suffered from retention of urine and from frequent and severe attacks of diarrhea. There was entire loss of sexual desire. There was no weakness or ataxia of the upper extremities, but he complained of progressive weakness of the lower extremities, which had begun about a year before. He had never had any twitching, or convulsions, or hyperesthesia, but he complained of a feeling of numbness from the waist down. His mental condition was unimpaired. The pupils responded both to light and to accommodation; the visual field was normal. There was no paralysis of any of the cranial nerves. Coordination in the lower extremities was impaired: the patient was unable to stand erect, and fell to the floor unless he had some support. There was no ataxie nor hypertyrophy of the muscles. The gait was decidedly ataxic, and the patient could not walk at all without assistance. There had been a gradual increase of sensibility to touch and pain in both feet, more pronounced in the right one. The knee-jerks on the right side were entirely abolished; on the left side it was normal. On May 27th the patient had been found to have a large bed-sore over the sacrum. From this time on he had rapidly become weaker, and had died on June 3rd.

Dr. Van Gieson, who had made the autopsy, reported the result of the histological examination. The lesion had proved to be an extramedullary tumor of the spinal cord, cylindrical in appearance, extending from a little above the second lumbar segment downward into the cauda equina, a distance of nearly three inches. It measured three centimetres at its broadest part. It rested on the ventral surface of the cord, and at the level of the fourth lumbar segment the pressure of it had begun to produce some distortion of the cord; at the fifth lumbar segment this distortion was very striking, both the anterior and posterior horns being pressed into a thin mass. In the sacral region the pressure-effects were less marked. The extreme tip of the cord was found to be curved upward on itself as far as the fifth sacral segment. Whether this retroflexion of the cord had been produced by the growth, which perhaps had developed from below upward, Dr. Van Gieson did not know.

The growth had proved to be a gliosarcoma. In connection with the paper, Dr. Van Gieson exhibited a number of charts and drawings of microscopical specimens.

The President stated that the patient had been under observation for so short a time that a diagnosis of tumor of the cord had not been made. The history of syphilis, the diplopia, and the ataxic gait had led the physician in charge to make a diagnosis of locomotor ataxia. Some of the characteristic symptoms of extramedullary tumor, such as radiation pain from compression of the nerve-roots, as well as pain in the back, had been absent. It was to be regretted that the correct diagnosis had not suggested itself, as it might have led to a more careful distinguishing of the symptoms, and perhaps even to operative interference.

Dr. SACUS said it was unfortunate that the history was so unsatisfactory, inasmuch as the growth had been entirely extramedullary. In tumors of the cord, it was always an important point to determine whether the growths were intramedullary or extramedullary, because the latter were unquestionably much more appropriate for operative interference. He inquired of Dr. Van Gieson whether an operation would probably have been of any avail in this case.

Dr. Van Gieson thought not. The growth was extremely vascular, and in certain parts of its course it had been wrapped about the cord.

Dr. M. Allen STARR stated that one of the most valuable symptoms in the diagnosis of extramedullary tumors of the
spinal cord was pain. In two such cases that he had seen this symptom had been very marked, and it had led to a correct localization of the growth. In both instances the pain had been referred to a limited area covering the field of distribution of the appropriate sensory nerves. In the first case, in which an operation had been performed by Dr. McCosh, a sarcomatous growth had been found in the dorsal region. The patient had gone into a state of collapse and had died ten days later of exhaustion. The second patient had been a young woman who had been operated on by Dr. McBurney, who had found the cord compressed by an encapsulated tuberculous deposit. The removal of this had resulted within three days in complete relief from the paraplegia from which she had suffered; she had also been thus enabled to perceive sensations in an area that had previously been anesthetic, and had regained some control over her bladder and rectum. This improvement had continued for four weeks. She had then had an attack of acute gastritis from eating some candied, and on the following day her temperature had been very high and the symptoms of paraplegia had again developed. They had gradually increased during the next ten days, and it had then been decided to reopen the wound, and the tissues about the cord in that region had been found to be so completely infiltrated with tubercular deposits that nothing could be done.

Dr. Sachs called attention to the fact that in this case the growth had covered the ventral surface of the cord; pain was only present when the growth was on the dorsal aspect or encroached on the posterior nerve-roots. In the diagnosis of these cases we should not rely so much on the presence of pain as on root symptoms.

The President said that in the case reported the man had complained of little or no pain. There had been no shooting pains characteristic of involvement of any of the nerve-roots. There had been a gradual loss of power in the lower extremities, which had become complete ten or twelve days before death, showing a compression myelitis.

Dr. Heber said the diagnosis in these cases was often very difficult. Still, he did not see how the symptoms had pointed to locomotor ataxia; the rapid progress of the disease, the lack of sensory symptoms, the motor symptoms, their unilateral character—these certainly had not pointed to tabes. The speaker agreed with Dr. Starr that pain was an early and very constant symptom in cases of tumor of the cord; it was perhaps the most important symptom of all. Where the tumor involved the cord substance, one was apt to find a rather characteristic symptom—namely, marked contracture, either on the side affected or on both sides.

PHILADELPHIA ACADEMY OF SURGERY.
Meeting of November 5, 1884.

The President, Dr. William Hext, in the Chair.

Ligature of the Spermatic Cord in the Treatment of Hypertrophy of the Prostate Gland.—This was the title of a paper by Dr. J. Ewing, who stated that in the male subject the function of the generative apparatus involved the secretion of semen and, under certain conditions, its evacuation. The former was accomplished in the testes and the latter by the vasa deferentia, the vesicula seminales, the prostate, the urethra, and the penis.

In order to explain certain forms of hypertrophic changes occurring in the prostate gland, he thought it necessary to consider the anatomical structure of the ejaculatory apparatus. Portions of this were tubal in character, forming ducts or canals, such as the vasa deferentia and the urethra; the vesicen-
agent—of giving increased propulsive movement to the column of fluid which, it might be, came only from the seminal vesicles or from both vasa deferentia and seminal vesicles. Was the hypertrophy, therefore, conservative in character, occurring at a period of life when nerve power declined and the other muscular portions of the ejaculatory apparatus yielded to the law of atrophy?

Dr. Mears had observed that the form of hypertrophy under discussion occurred in those who had overindulged the sexual appetite—who had kept the generative organs in prolonged states of excitement with, in many instances, incomplete acts, or without acts of colition, these conditions resulting in over-stimulation of the gland.

The plan of treatment suggested, he said, would appear to be both philosophical and physiological, as an effort had been made to show that the pathological condition present was directly associated with the functional activity of the generative apparatus. Observe this, and all organs associated in the performance of this function would be affected. Without the organs for the secretion of semen the ejaculatory apparatus had no function.

The eminent Bukitansky had long since observed that the prostate was generally found to be small when the organs of generation were in an imperfect condition, and a diminution of the prostate with relaxation of the glandular tissue had been observed as accompanying atrophy of the testes.

To obliterate the function of the generative apparatus was therefore a rational method of treatment in prostatic hypertrophy of the forms above mentioned. How could this be accomplished? Dr. J. William White, in an elaborate paper on The Surgery of the Hypertrophied Prostate, read before the meeting of the American Surgical Association in 1888, had referred to the operation of castration as a therapeutic measure in hypertrophy of the prostate, and had reported a number of experiments which had been conducted on dogs, showing that removal of the testes in these animals had been followed by prostatic atrophy. Without doubt castration would prove effectual in the production of atrophy, and reports of cases had appeared in recent current surgical literature in which very positive relief had been afforded by the operation. It was an operation, however, to which patients would naturally refuse to submit, unless in the very last stages of disease of the bladder resulting from prostatic obstruction.

In the discussion which followed the reading of Dr. White’s paper Dr. Mears had suggested ligature of the vas deferens as an operation which would probably be as efficacious as castration, and one which he believed would be more readily accepted by patients. He had seen the report of one case in which this operation had been performed since that date with a successful result.

Within the last year he had taken occasion to examine patients on whom he had performed subcutaneous ligature of the vessels of the cord for varicocele, and he had observed more or less atrophy of the testes in these cases. In all the vas deferens had not been excluded from the ligature. One patient, who was eighteen years old at the time of the operation, had reported that, subsequent to the operation, nocturnal emissions, from which he had suffered greatly, had disappeared, showing, he thought, the relief afforded to prostatic irritation by the operation.

Inclusion of the vas deferens in the ligature applied to the vessels of the spermatic cord would, he believed, produce atrophy of the testes, and the operation was not increased in gravity. It might be advisable to apply the ligatures at intervals of time.

The gradual disappearance of the sexual function would not disturb the mental condition of the patient, as many realized it from other causes, and the consolation he would derive from the presence of testicles, with relief from suffering, would, he believed, fully compensate. In all cases the patient should be informed of the character of the operation, and what was intended to be accomplished by it. With him should rest the decision. Dr. Mears regarded it as the duty of the surgeon, however, to urge very earnestly the performance of any operation which would be efficacious in terminating the sufferings, sometimes horrible, of patients suffering from the results of prostatic obstruction.

Dr. Charles B. Penrose stated that during the last eighteen months ligature of the uterine arteries had been used to replace oophorectomy for small fibroid tumors of the uterus. The result of ligature of both uterine arteries seemed to show as quick and permanent atrophy of the tumor as followed removal of both ovaries. The subject was, however, still too recent to enable us to come to any definite conclusion. A good many patients, even in the hands of enthusiastic advocates of castration for fibroid tumors, failed to be benefited. Taint, he thought admitted that there were from five to six per cent. of failures.

Dr. Mears, he thought, had said that fibroid tumors were more common in married than in single women. The speaker thought, however, that Dr. Emmett and Dr. Goodell made an opposite statement, and attributed the growth of fibroids to the congestion due to ungratified sexual desire or to uninterrupted menstruation.

Dr. Orville Horwitz had had no practical experience with this operation, but expected to operate in two cases. If the cord was to be completely ligated, he thought it would be wiser to tie it above and below and divide it, as was done for the radical cure of varicocele. It was maintained that the open operation was the safer one, because if more than two thirds of the veins were tied at one time, atrophy of the testicle was apt to occur. He had seen one or two cases where marked atrophy of the testicle had followed subcutaneous ligature of the veins.

Another point to be considered in the ligature of the entire cord was in regard to the blood supply of the testicle. Dr. Mears thought that the attachments of the testicle would be sufficient to nourish it. The speaker was strongly inclined to try this operation, but he should prefer to employ it first on one of the lower animals, to see if gangrene of the testicle would follow.

Dr. Mears said that his paper had been largely suggestive. He thought it would be very desirable if we could obtain an operation as free from danger as ligature or section of the cord, and which would give positive relief in the cases of prostatic hypertrophy alluded to. Extirpation was an operation to which patients would not readily submit. He thought if we could leave the testicles in position a great point would be gained. It was absence of the testicles which disturbed the feelings of the patient. If the sexual function gradually disappeared it would not excite the same mental disturbance.

He was familiar with Dr. Emmett’s and Dr. Goodell’s views with reference to the occurrence of fibroid tumors in unmarried women. His statement had not related to the cause of fibroid tumors, but to the manner in which they, being present, were affected in unmarried women. In his own practice he had observed cases where the tumors had greatly increased in size in married women, and in unmarried women where there had been reason to believe they had indulged the sexual appetite.

Lithotomy after Partially Successful Closure of Extrophy of the Bladder; Subsequent Construction of a Perineal Urethra from Scrotal Tissue.—Dr. John B. Roberts read a paper on this subject.

In March, 1893, a child, aged eight years, with extrophy
of the bladder, had been brought to him at the Polyclinic Hospital for treatment. The mother had told him that when three or four years old he had been operated on at the Children's Hospital. It had been evident that some improvement in the condition had been made by this early operation, because the posterior wall of the bladder did not protrude, as was often the case, but formed a rather shallow cup at the base of the rudimentary penis. The flaps had evidently been taken from the surface above the congenital defect and at its two sides, as in Wood's operation, for the clefts in these regions had been apparent. The urine had run from the bladder over the penis and scrotum, and had also escaped from linear sinuses along the top and sides of the thickened tissue which had closed the upper portion of the cleft in the bladder.

As a first step in the operation he had endeavored to produce a perineal fistula by thrusting a curved needle from the base of the bladder through the perineum, behind the scrotum, and conducting a drainage-tube through the opening so made. The tube had been increased in size at various intervals until at the end of two months there had been a canal which would contain a rubber urethral bougie of moderate size.

He had then etherized the patient a second time, and had made a circular incision around the edge of the open bladder. The rudimentary penis, consisting of the spongy body, the cleft glans, and the cleft prepuce, had been entirely removed. Cylindrical masses on each side of the opening in the bladder, which had appeared to be the representatives of the cavernous bodies, had also been dissected away. A piece of soft-rubber esthetor had then been introduced through the perineal opening established by the first operation, and its end allowed to reach the floor of the bladder. The purpose of this procedure had been to secure downward drainage of the urine after the edges of the bladder had been brought together.

Seven deep sutures had next been inserted in such a manner as to bring the denuded edges of the bladder wall into apposition in a vertical direction. The wound had then been sealed with isoform and collodion.

The perineal tube, however, had soon become blocked with mucus and pus, which had been continually flowing from the irritated mucous membrane of the bladder, and had not been satisfactory as a drain. The speaker had finally passed a drainage-tube from one of the upper sinuses directly through the bladder and out of the perineal opening, in order to prevent the sutures in the middle line from yielding. These middle sutures, however, had finally given way, and when the patient passed from observation there was a large opening in the middle of the attempted closure. Some union had, however, been obtained. The perineal opening had shown a marked tendency to close.

He had not seen the patient again until October, 1894, sixteen months later. At this time the perineal opening had entirely closed and its scar was inconspicuous, but the exostrophy of the bladder had been completely covered by the new anterior wall. At about the middle of this wall, which had been constructed in the manner described, was a small opening of sufficient size to admit the end of a large probe. At the upper and right-hand side of the portion of the wall which had been constructed in infancy was a linear sinus about an inch in length. This was situated at one of the points which, when he had first seen the child, had allowed the urine to escape. There had been a little oozing of urine from the small central fistula, but the major portion had escaped from the sinus at the upper right-hand border.

The mother said that the patient had suffered severe pain, which had been evident by his crying at the least touch of the skin in the neighborhood of the central sinuses. The insertion of a probe had proved that the new bladder contained calculus. The child's general condition had been poor, and it had been evident that he had suffered greatly. The offensive character of the urine and the difficulty of keeping him free from its odors had caused the speaker to give him small doses of turpentine which, as was well known, imparted a peculiar agreeable odor to the urine. This device had seemed to render the patient less offensive to the others in the ward.

A few days later Dr. Roberts had enlarged the opening in the middle of the bladder wall in front and had found the cavity filled with calculi. They were ten in number and varied from five sixteenths to five eighths of an inch in diameter. Their combined weight when not dried was a hundred and ninety-five grains.

It had seemed to him that the establishment of a perineal urethra lined with skin would afford efficient drainage to the new bladder, and would remain patent. He therefore had determined to cut a channel between the perineum and the floor of the bladder, and turn in flaps of skin taken from the scrotum. As a first step he had incised the scrotum in the middle line and had removed both testicles. He had then made a puncture downward from the base of the bladder to this scrotal incision. This had permitted him to utilize the scrotal tissue for lining the new channel. By two horizontal incisions on each side of the opening he had obtained strips of scrotal skin and superficial fascia half an inch wide and an inch and a half long. To the inner edge of these, ligatures had been tied, and the threads carried upward through the new urethra. The cutaneous flaps had then been drawn up along the canal into the bladder, and had been sutured on each side of the incision in the middle line of the anterior bladder wall. This maneuver had lined both sides of the perineal opening with skin from the perineum to the anterior bladder wall. A drainage-tube had been inserted to keep the channel patent, and the bladder and tube had been washed out.

No attempt had been made to close the opening in the middle line or that at the upper and right-hand side. He had deemed it better to leave these open for convenience in flushing the foul bladder cavity. It had been his intention to close these at a later period. The edges of the wound in the perineum left by the plastic operation had been brought together with sutures and it had healed promptly. Antiseptic solutions had been used for washing out the bladder and tube, and the patient had done well for several days. His temperature had not been high and the drainage through the perineal tubes had been quite satisfactory, though not always perfect. At the end of three or four days he had begun to lose his appetite and had vomited occasionally. He had died on the fifth day, apparently from exhaustion.

An autopsy had shown disease of the left kidney, which had been riddled with small abscesses. The ureter on this side was double, and showed great enlargement of the caliber and thickening of the walls. The pelvis of the kidney and the double ureter were filled with pus. Just before the two ureters of this kidney reached the bladder they united and opened into the bladder by a single orifice. The right kidney and ureter appeared to be normal.

He believed this method of constructing a perineal urethra and lining it with skin from the scrotum would be found an efficient device in dealing with these unfortunate cases. It was very probable that the child would have lived if he had taken this step originally, instead of making an opening into the perineum without a cutaneous lining.

Dr. H. R. Wharton asked Dr. Roberts if it was not possible that these stones might have had some connection with the growth of hair on the inverted flap. In Wood's operation the
inverted flap often contained hairs, and these might continue to
grow as the patient increased in age, and become the seat of
calcareous depositions from the urine.

Dr. L. W. Stellwag asked Dr. Roberts what his theory
was in regard to the formation of these calculi? What was
their nucleus? He recalled a case of vaginal hysteroctomy
where a portion of the posterior wall of the bladder had been
removed. Within a week the stitches closing the bladder opening
had been covered with deposits of considerable size, and it
had not been an easy matter to remove the sutures, incrusted
as they had been.

Book Notices.

A Clinical Manual of Diseases of the Eye, including a Sketch
of its Anatomy. By D. B. St., Jons Roosa, M. D., II. D.,
Professor of Diseases of the Eye and Ear in the New York
Post-graduate Medical School and Hospital, etc. Illustrated
by One Hundred and Seventy-eight Engravings and Two
Chromo-lithographic Plates. New York: William Wood

The author says truly that there are already many excellent
treatises on the eye in the English tongue, but every ophthal-
mologist will welcome this book because of the personal color-
ing of such an indefatigable and clear-headed observer as Dr.
Roosa. The first part, on the anatomy of the eye, is by Dr.
Davis. It occupies a hundred and sixteen pages and presents
this very important basis of ophthalmology, which is too often
omitted from works of this class, in as lucid and readable a
form as comports with the brevity of his space.

The second part is devoted to the relative frequency of dif-
cerent diseases of the eye, the methods of examination, therape-
tsics, and surgery. The tables showing the relative fre-
cuency of diseases are very interesting, and one is particularly
struck with the figures regarding the proportionate increase of
 refraction cases. In 1870, at the New York Eye and Ear In-
firmary, only 2.5 per cent. of eye cases were cases of refraction.
In 1892 they had increased in the same institution to 19.8 per
cent, and at the Manhattan Eye and Ear Hospital they amounted
to 31.3 per cent. Either the percentage of such cases is in-
creasing or we are accustomed to make more thorough exami-
nations than formerly.

The chapters on the examination of the eye do not differ
materially from similar portions of other works. A consid-
erable space is devoted to the description of the Javal-Schiotz
ophthalmometer. This is naturally to be expected by every
one conversant with Dr. Roosa's enthusiastic advocacy of this
instrument. In this description exceptions may be taken to a
few points. On page 157 he says: "Following the rules
above, the long index always indicates the axis of the convex
glass to be worn, and the short index on the reflectors the axis
of the concave glass that is ordered—in any case." (Italics,
Dr. Roosa's.) Competent observers occasionally meet with
cases in which the axis of the corneal astigmatism as shown by
the ophthalmometer and the axis of the total astigmatism as
shown by the test-lenses are not the same. In such cases must
ophthalmologists prescribe glasses in accordance with the read-
ing of the test-lens. On page 160 he says: "If no astigmatism
at all exists, there is no overlapping and no separation on the
second turning." Many observers find that when there is no
overlapping or separation of the wires the patient will usually
be benefited by +5 D. or —5 D. according to the rule.

"However much special knowledge the practitioner may
have of the anatomy and physiology of the eye, and of its local
symptoms when diseased, he must have a good knowledge of
and experience with the symptoms of constitutional or general
disease, or he will fail in attempting to become a competent
specialist." If every young graduate could have the truth of
these words impressed upon him so that he would know it to
be an actual, incontrovertible fact, fewer of them would seek to
enter the specialty until they were competently prepared.

We are glad to see Dr. Roosa, on pages 187 and 188, take so
strong a position in advocacy of antisepsic precautions of the
strictest kind previous to operations. Whether a solution of
boric acid or one of bichloride of mercury is used with which
to bathe the eye is unimportant so long as absolute surgical
cleanliness, the sole object of all antisepsic precautions, is main-
tained. But we regret to find him, in another part of the book,
class among "operators who lay great stress upon antisepsies"
some who "will operate upon the eye in aprons or gowns
which they have worn while treating contagious cases." Such
operators should never be mentioned as laying great stress upon
antisepsies, no matter how or how much they talk or write
about them.

The chapter on surgical operations is excellent. The space
given in some books to operations of mainly historical value is
here devoted to practical details. But under the head of plastic
operations the omission of Thiersch's method of skin-transplantation
is to be regretted, as it is probably the most valu-
able advance that has been made in this line for many years.

In the description of the diseases of the eye Dr. Roosa has
followed the example of Stellwag in giving the brief character-
istic description in Italics, a plan which is of valuable assistance
to the reader. The frequent references throughout indicate
the great extent of the author's research as well as his fairness
in quoting the opinions of younger men with whom he has been
associated.

The chapters on cataract are good. The author prefers
Forster's method for the ripening of cataracts and believes that
the iridectomy rather than the trituration is the main factor in
producing maturity. The treatment advised after cataract ex-
traction is sensible, as is also the discussion of methods advan-
ced by some prominent men.

In the fourth part, which is devoted to the conditions of
the eye requiring the use of glasses, there is an excellent dis-
section on asthenopia, a careful perusal of which might possi-
bly repay some who write voluminously on the subject.
Regarding the rest, it may be said, as, indeed, of most of the book,
the same faults may be obtained elsewhere, but in very few
books will they be found more lucidly stated or more practi-
cally expressed.

The glossary at the end gives the derivation of the techni-
cal words used in ophthalmology. Illustrations are not over-
abundant, but some of them are very good. The book is well
put up, uniform with the same author's work on Diseases of
the Ear. We can heartily recommend it.

Obstetric Surgery. By Eberit II. Grandin, M. D., Obstetric
Surgeon to the New York Maternity Hospital, etc., and
George W. Jarman, M. D., Obstetric Surgeon to the New
York Maternity Hospital, etc., With Eighty-five Illustra-
tions in the Text and Fifteen Photographic Plates. Phila-
[Price, $2.50.]

This work is almost unique among American books, both in
subject matter and in method of treatment. A strong surgical
tendency is apparent in all departments of medicine, and obstet-
ries is not an exception. There can be no doubt that timely operations in obstetrics may secure results as brilliant as those now obtained in general surgery, provided equal care is exercised in the selection of cases and in the details of operating. The authors are strenuous in their insistence upon asepsis in every detail, not only in obstetric surgery, but in the management of the puerperal state, believing that aseptic obstetrics "rolls labor of its terrors and the puerperal state of well-nigh its sole risk."

The book is free from literary references, elaborate statistical data, and profitless discussions of disputed points. The authors, being teachers, have written from a teaching basis. Their style is concise and graphic and they have succeeded admirably in their descriptions of the various operations. Their work can not fail to prove of value to the obstetrical practitioner, as it presents the most recent and approved methods of managing some of the most serious conditions with which he is brought in contact. The following topics are discussed: Obstetric asepsis and antisepsis, dystocia and its determination, artificial abortion and the induction of premature labor, the forceps, version, symphysiotomy, the Cesarean operation, embryotomy, the surgery of the puerperium, and ectopic gestation.

The present number of this admirable work is devoted to the thyroid treatment of skin diseases and to acute poliomyelitis. The author was led to the use of thyroid extract in skin diseases by the extraordinary improvement observed in the nutrition of the skin in myxedematous patients who were receiving the thyroid treatment. In them the harsh, rough, dry skin became smooth and soft, so that practically a new skin was formed in some cases. He reports twenty-one cases of the thyroid treatment of psoriasis. The plates show marvelous improvement in many instances. The author's conclusions are that in a large proportion of cases the thyroid treatment produces a temporary cure. In some of his patients the improvement was rapid, in others slow. In a few cases no improvement was observed, and in others the result was not permanent. The results obtained in five cases of lupus show that this treatment is capable of producing considerable improvement in that disease.

Poliomyelitis is discussed with the painstaking care characteristic of all this author's work, and the article on it is especially satisfactory. The plates are fully equal to those of former numbers, and are the most notable feature of the work.

BOOKS, ETC., RECEIVED.

Materia Medica and Therapeutics for Physicians and Students. By John B. Biddle, M.D., Late Professor of Materia Medica and General Therapeutics in the Jefferson Medical College, Philadelphia. Thirteenth Edition, revised, rearranged, and enlarged. With special reference to Therapeutics, Toxicology, the Physiological Action of Medicines, and containing all the Preparations and Remedies described in the United States Pharmacopæia of 1890, to which the work has been made to conform. By Clement Biddle, M. D., Medical Corps, United States Navy. With Numerous Illustrations. Philadelphia: P. Blakiston, Son, & Co., 1895. Pp. 5 to 714. [Price, $4.]

Transactions of the American Orthopedic Association, Eighth Session. Volume VII.

Omphalorrhagia—Umbilical Hemorrhage. By C. B. Lyman, M. D., Denver. [Reprinted from the Denver Medical Times.]

Tumor of the Cerebellum. With Bulimia and Recurrent Apoplectic Seizures. By J. T. Eskridge, M. D., Denver. [Reprinted from the Boston Medical and Surgical Journal.]

The Treatment of Acute Coryza.—The Journal des praticiens for January 26th publishes an article on this subject by M. Marcel Lernoyez, who remarks that there is a very widespread opinion that coryza is always a benign affection that does not call for treatment, and, moreover, that therapies has no influence over it, a double mistake of which many persons have been the victims.

Acute coryza, says M. Lernoyez, from a pathological point of view, should not be neglected. It may leave in its place a chronic parulent discharge, or predispose the patient by repeated attacks to hypertrophic rhinitis; and its effects which manifest themselves in other parts are still more to be feared. Occasionally it spreads to the lacrimal sac or to the frontal sinuses and causes persistent suppuration. Or, again, it infects the middle ear and leads to the necessity of trephining the mastoid; finally, it is very often the origin of descending bronchopulmonary infection.

Medicine, says the author, is not so powerless against coryza as is supposed. It may moderate the disease at the outset; it may palliate painful symptoms in a marked degree; and very often it may prevent the complications which are provoked by coryza. There are innumerable abortive remedies and certain local means which, if employed when dryness of the mucous membrane is first observed, give excellent results. But, if at the end of twelve hours their effect is not visible, their use must be stopped, as their irritating action, if kept up, will increase the intensity of the coryza. An excellent solution for inhalation, known as Brandt's remedy, is the following: Pure carbolic acid and ammonia water, each, 75 grains; alcohol, 350 grains; distilled water, 225 grains. Every hour ten drops of this solution should be poured on blotting paper and the vapors inhaled by the nose for several seconds.
Among the abortive powders the following, which should be very finely pulverized, is preferred by M. Lermoyez: Cocaine hydrochloride, 8 grains; menthol, 4 grains; salol, 75 grains; boric acid, 225 grains. A pinch of this is to be snuffed up every hour; it provokes an abundant mucous discharge and affords great relief.

Among the internal abortive remedies there is only one, says M. Lermoyez, that is comparatively reliable, and that is the mixture, in equal parts, of tincture of belladonna and tincture of aconite root, of which thirty drops are to be taken in divided doses. Energetic sweating, also, induced by a vapor bath has occasionally given beneficial results. These abortive means are sufficient in ordinary cases. In certain subjects, however, coryza brings, almost inevitably, with each attack, serious otic or bronchitic symptoms, and more energetic means are required. The patient should remain in bed, and revision should be practiced on the legs: abundant perspiration should be brought on by means of hot alcoholic drinks, by a potion of ammonium acetate, or by Dover's powder.

If the coryza itself can not be moderated, the most painful symptoms, which are nasal obstruction and headach, may be ameliorated by the pellatiive treatment. For this nothing is so good as the use of a Richardson spray with a boiled and tepid one-per-cent. solution of cocaine hydrochloride; this brings real relief, freeing the nose and at the same time suppressing the pain in the head. Spraying every two or three hours is sufficient. The cocaine may also be incorporated in powders that are slightly antiseptic but not irritating. The following formula is given: Cocaine hydrochloride, 8 grains; menthol, 4 grains; bismuth salicylate and sugar of milk, each, 75 grains. If there is reason to fear cocaine poisoning, 30 grains of pure olive oil and 30 grains of menthol may be administered by the spray and not by painting, which may produce an erosion, especially if the patient attempts to do it himself.

In order to quiet the neuralgia of the trigeminal nerve which often accompanies coryza, says M. Lermoyez, as well as to combat the general infection which manifests itself in chills and lamaguo, a capsule containing four grains of quinine hydrochloride and eight grains of antipyrine is to be taken at each meal. To prevent erthyema of the orifice of the nostril, the entrance of the nose and the upper lip should be rubbed with vaseline with which boric acid has been incorporated. Finally, several hygienic prescriptions are indicated. If there are no general symptoms, the patient may go out; if there is fever, he should remain in his room. He must avoid sneezing as much as possible, and refrain from blowing his nose too energetically, as there is danger of projecting septic maceeties into the middle ear. Irrigation of the nose at the acute period of coryza should be absolutely interdicted, as it results in a constant irritation of the mucous membrane and increases the tumefaction; furthermore, it constitutes a real danger for the ear. On the other hand, it finds its indication afterward when a mucous-purulent secretion follows coryza, which tends to become chronic. Then the treatment should be the same as that employed in chronic purulent rhinitis.

The prophylactic treatment, says M. Lermoyez, has a great importance for certain persons in whom coryza sets in on the least exposure to cold. These persons should become accustomed to the inclemency of the weather; they should exercise in the open air; and cold douches and salt-water baths should be taken; at the same time underclothing and stockings of wool, also shoes with heavy soles, should be worn. The chronic lesions of the nose, which are the starting point of acute attacks of rhinitis, should be treated. These lesions are, ordinarily, adenoid growths in infancy and hypertrophic rhinitis in adults. It is not rare to find that among the latter ablation of the hypertrophied turbinals will cause the cessation of repeated attacks of coryza.

Acute coryza in the newborn, says the author, is a very serious affection. It disturbs the sleep and prevents the child from nursing, and the patient wastes away rapidly. In these cases the nasal obstruction should be removed at once by applying several drops of a two-per-cent. oll solution of menthol to the nasal fossa, which detaches the crusts at the opening of the nostrils and provokes momentary retraction of the turbinals. The mentholated oil, which is entirely harmless, is preferable to cocaine solutions, which, at that age, cause very serious toxic symptoms and should, for this reason, be proscribed.

Before the child nurses, the secretions which obstruct the nose should be removed by means of a dry douche given with a Politzer's bag. One moderate insufflation into each nostril is sufficient. This very simple procedure is preferable to nasal irrigation, which should be reserved for cases of purulent rhinitis. With regard to intubation of the nose, which consists in introducing into the nasal fosse rubber tubes to establish an air-passage, this is a dangerous method, says the author, which wounds the mucous membrane and gives rise to synechia. If the child, in spite of this treatment, can not breathe sufficiently through the nose to admit of its nursing, it must be fed with a spoon. The best prophylactic treatment for coryza in infants is not to allow them to go out too soon after birth, especially in damp weather; also, in bathing them, soapy water must not be allowed to penetrate the nose.

**Brachial Monoplegia due to Lightning-stroke.** — The Lyon médical for January 6th publishes an article on this subject in which the author, M. J. Collet, relates the following case of a man who had been struck by lightning: The entire left side was paralyzed and the patient had lost the power of speech, although he stated that he had not lost consciousness. After remaining in this condition for a few minutes he had gradually regained the power to speak and to walk, but the left arm remained paralyzed. There was no pain in either the head or the left arm, and there was no wound of either. When the patient entered the hospital he showed a very marked paresis of the left arm, which involved all the muscles equally. He could not lift the arm, and flexion of the forearm on the arm was almost as much beyond his power. The patient was inefable of resisting, without an effort, the least passive movement in a contrary direction, and the fingers were locked in the palm of the hand.

There was no appreciable atrophy of the muscular masses, which were very sharply defined, and there were no fibrillary tremors. The movements of the prominence of the shoulder were perfectly preserved; the movements of the right arm were normal; the legs were perfectly strong, and the patellar reflex was slightly exaggerated on each side. The tactile sensation showed no alternation, but the sensibility to the prick of a pin was manifestly diminished on both sides, perhaps a little more on the left side.

Another examination took place two weeks later, and an appreciable difference was found between the two sides in regard to the sensibility to pain, which still remained very dull. The patient's skin was brown and thick, he seemed to feel no pain on being pinched or pricked, and there was no anemia of the integument. Although a very careful examination was made, not the least evidence of pupillary inequality could be discovered. The sight seemed to be equally good in both eyes, but there was divergent strabismus. There was absolutely no contraction of the visual field.

The pharyngeal reflex was normal: pressure on the testicle did not provoke any abnormal sensation; the sensibility of the
cornea was found to be diminished; an examination of the viscera revealed nothing, and the general condition was good.

An investigation of the electrical reaction, practiced a few days later with the interrupted current, showed no appreciable difference between the healthy side and the affected side. With the galvanic current, with the electrodes applied on the forearm, sometimes on the dorsal surface, sometimes on the palmar surface of the left side, with a current of five milliamperes there was a very distinct contraction on cathodic closure, and a very feeble contraction on anodic opening, not manifesting itself by a movement of the fingers.

The patient was subjected to daily applications of faradic electricity on the paralyzed arm, and when he left the hospital there was only a slight paresis, and the sensibility of the cornea was normal.

There was in this case, says the author, no previous history of nervous trouble. The patient had been struck by lightning and completely paralyzed for several minutes, after which there had been hemiplegia for a short time, and this had been followed by brachial monoplegia of the left side, which improved rapidly in fifteen days. Paralysis from such a cause is not absolutely rare, he says, but still there are other points of detail worthy of mention. It may be a question of a simple paralysis of traumatic origin, due to the fall. The patient stated that at the moment when he was starting to come down a ladder he had been thrown to the ground and immediately paralyzed. M. Collet says it may be admitted that the patient's left shoulder struck the ground and that the brachial plexus was stretched and bruised by a forced movement of the collar-bone, below and behind, or by some other mechanism, thus causing an equal paresis of all the muscles of the arm. But this hypothesis is hardly probable, says the author. At first the patient could not indicate the spot on the body which had been struck in the fall. He stated that he had fallen only a short distance and that there had been straw on the ground, and finally that at no time had he felt any pain in the shoulder or in the arm on the paralyzed side. The examination had revealed no trauma, no contusion, no scratch, and no myosis of the left side, all of which are symptoms that are frequently found in inferior radicularen paralysis. The want of difference between the electrical reactions of the two sides, says M. Collet, is not perhaps of very great diagnostic value, as the investigation was not made immediately after the patient's entrance into the hospital. The mode of invasion of the paralysis, however, seems to the author to be conclusive. It is difficult to attribute to the fall the appearance of this complete paralysis, with loss of speech, giving place in a few minutes to a left hemiplegia, which finally extended to the left arm. But the question of all traumatic mechanism put aside, it may be asked if there was not another factor which played its rôle in the production of this paralysis; if hysteria was not a cause.

The idea of the possible rôle of hysteria in paralytic manifestations following fulguration is of comparatively recent date, and it was introduced through the efforts of M. Charcot and his pupils. Among cases of paralysis following a stroke of lightning there are some that have nothing in common with hysteria, but, on the other hand, there have been found some cases which distinctly bore the impress of neuroses. There are some cases in which hysteria shows itself distinctly, and there are others where its presence is very doubtful, notably those where the paralysis lasts for only a few hours or a few days, where it is not accompanied by any hysterical mark. Stricker, Knapp, Leyden, and Ross have cited cases in which they attributed the paralysis of shock from lightning to a direct concussion of the brain or of the medulla oblongata. Observations of this sort are numerous, but from the point of view mentioned they are of very unequal value, and it is all the more difficult to form an opinion from reading of them, as the majority of the cases date from a period when little was known of hysteria in men, and when the presence or absence of hysterical marks are not mentioned except in a cursory manner.

The rôle which hysteria plays in the paralysis due to fulguration remains, then, well established, says the author, but an exact idea of the proportion of cases in which it may take part can not be given.

Without wishing to draw any general conclusions from this particular case, says M. Collet, it seems to him that the paralysis here was due to the simple action of the lightning in a person not predisposed to hysteria, and that it was a case of paralysis due to fulguration and not hysterical monoplegia following fulguration, or a neurosis due to a special traumatism. However, it is not irrational to suppose, he says, that the shock from the lightning may have given rise to a disturbance of the nervous system sufficient to produce dynamic troubles, as it may in other cases arouse a neurosis which, up to that time, had remained dormant.

The Phenolates of Bismuth.—The Province médicale for January 19th contains an article on the action of certain phenolated compounds of bismuth — phenol-bismuth, cresol-bismuth, and beta-naphthol-bismuth. M. Jasenski, who has made a study of these compounds at the laboratory at St. Petersburg, gives the following results: 1. Phenol-bismuth contains 27.5 per cent. of bismuth and 22 per cent. of phenol. 2. Meta cresol-bismuth contains 75 per cent. of bismuth and 17.5 per cent. of meta cresol. 3. Beta-naphthol-bismuth contains 71.6 per cent. of bismuth and 23 per cent. of naphthol. 4. Tribromphenol-bismuth contains 44.8 per cent. of bismuth and 51 per cent. of tribromphenol.

The author has seen these substances become decomposed in the stomach under the influence of the gastric juice, on the one hand, into phenol, cresol, and naphthol, and, on the other hand, into bismuth.

One part of the compound, not having time to become separated in the stomach, passes into the small intestine, where it finds conditions which favor its complete decomposition by the acid of the intestinal contents.

The phenol and cresol, separated from the bismuth, are entirely absorbed in the digestive canal, and are eliminated by the urine in a condition of a conjugate sulpho-acid or combined with glycuronic acid. With regard to the naphthol, one part passes into the urine and the other part into the digestive canal and is expelled with the feces.

The quantity of hydrochloric acid contained in the gastric juice being greater in dogs than in man, in them a small part of the bismuth becomes transformed into a soluble compound (bismuth chloride), and is absorbed and then eliminated by the urine, while the larger part passes into the fecal matter in a condition of bismuth sulphide.

In man's urine no bismuth is found, but it is met with in the feces in the proportion of 0.014 per cent.

Notwithstanding the toxic properties of the phenols, not one of these preparations, when administered to a person to the extent of 75 grains, or to a dog to the extent of 150 grains a day for a period of three weeks, had any noxious effects; probably, says M. Jasenski, because the separation of the phenol from the bismuth took place slowly.

The employment of these compounds in the treatment of acute and chronic diseases of the digestive canal or of the various infectious diseases gives good results, for we have the association of a general carbolized antiseptic and the bismuth as a local antiseptic.
FEMORAL ANEURYSM,
BEGINNING IMMEDIATELY UNDER POUPART'S LIGAMENT
TREATED BY DIGITAL COMPRESSION.
RECOVERY.

By HENRY W. SAWTELL, A. M., M. D.,
SURGEON, U. S. MARINE-HOSPITAL SERVICE.

Seaman J. M., aged twenty-eight years; nativity, Newfoundland; was admitted to the United States Marine Hospital, port of Boston, on September 15, 1894. He complained of a swelling in the left groin which was at times painful and pulsated. The patient was under the impression that it was a bula, and applied for treatment for that disease. Inquiry revealed the fact that the tumor first made its appearance after a hard night's work at the wheel in a heavy sea about sixteen months ago. While at the wheel he was obliged to stand in such a position that he had to brace himself with his left leg, subjecting it to a considerable strain. Since it was first observed the tumor had increased in size.

Examination of the parts revealed a tumor, pulsating very forcibly and perceptibly, so much so that attention was directed to it as soon as the parts were exposed. By palpation it was found to have an expansile pulsation. The tumor was about the size of a hen's egg, of a fusiform shape, and extended upon Poupart's ligament, probably involving the extreme lower end of the external iliac. Pulsation was stopped by pressure on the artery above. The diagnosis of aneurysm of the femoral artery was at once made, and a course of iodides prescribed, with perfect rest in bed.

When questioned as to previous history the patient acknowledged having had syphilis, and gave the following history: During the fall of 1887 he had a chancre, which came on a month and eight days after exposure. The sore healed twenty-three days thereafter while at sea. He commenced to have various symptoms, such as an eruption over the body, neuralgia, and pain in joints, which disappeared readily under treatment, and he resumed his voyage.

I saw this case for the first time September 22d, and at once ordered compression of the artery on the proximal side of the aneurysm, and detailed Dr. Charles R. Robins, interne, to superintend the treatment; and the successful termination of the case was due to his watchful care.

Prior to the adoption of digital compression, attempts were made to control the circulation by means of a tourniquet variously applied, and also a roller bandage used as a compress over the artery just above the tumor, using a relay of convalescent patients to hold it in place. But these attempts proved futile, only tending to make the parts very sore, and a very slight congestion, if any, was effected. It was decided to desist from further attempts until the tenderness had disappeared, giving in the meantime veratrum viride to control the circulation, and elevating the leg on pillows.

On October 4th, all soreness gone, compression was commenced with the thumb directly over the proximal side of the sac. The thumb of one hand made pressure on the artery as it passed over the brim of the pelvis, and this thumb was strengthened by pressing on it with the thumb and different fingers of the other hand. Six centigrams of morphone were administered hypodermically before commencing the operation.

At 1:30 p.m., after two hours, no pulsation could be distinguished. Pressure, however, was continued until 6:20 a.m., October 6th, making forty-three hours of pressure, forty-one of which were after pulsation had ceased. Three relays were used, the last of hospital attendants. The patient was catheterized during this time as it became necessary. Nineteen centigrams of morphone were administered hypodermically. This relieved the pain, caused the patient to sleep, and made the case more manageable. No bad effects were produced further than a slowing of the respiration. After compression was stopped, the thigh was brought up to right angles to the body and held in this position with a bandage. When the effects of the morphine had passed away, drop doses of neomine were given and the iodides continued. The patient was kept on low diet, and not allowed to exert himself or leave the bed. On October 27th the patient was allowed to walk about for the first time after being three weeks in the recumbent position, and expressed himself as feeling entirely recovered from the troubles incidental to the affection. He was discharged from the hospital October 29, 1894, at which time the parts were examined and the tumor was found to be about half its former size, and the clot appeared to be thoroughly organized. No pulsation of femoral, popliteal, or tibial arteries could be detected, but the collateral circulation was thoroughly established, as evidenced by the warmth and absence of edema, and the full usefulness of the limb.

The history of this case teaches that pressure can be more successfully maintained by the thumb, assisted by the other hand, than by the intervention of any appliance, and that pressure should be persisted in until the collateral circulation has been fully established by the enlargement of the arteries entering into it. Hence it was deemed advisable to continue pressure for some considerable time after pulsation in the sac had ceased.

Without entering into a discussion of the varieties, etiology, symptoms, and pathology of aneurysm, it is nevertheless interesting to note briefly the history of the principal forms of treatment that have prevailed from an early period up to the present, in connection with my case just narrated. This résumé has been compiled mainly from American surgical works. The only operation for aneurysm known to the ancients consisted in the laying open of the tumor by incision, and after turning out its contents applying the hot iron to the extremities of the affected artery so as to seal up their mouths. The result was that almost every patient died from hemorrhage. This practice continued up to the third century, or until the time of Antyllus, who adopted a more rational method. He freely opened the tumor, cleared out its contents, and tied the artery above and below. The sac was then stuffed with charpie to promote suppuration and occlusion, the object being to heal the wound from the bottom. Occasionally the tumor was extirpated. The result of this operation was most disastrous, though it has again received attention of late. Many perished from the effects of inflammation, some of secondary hemorrhage, and not a few from the shock of amputation made as a last

* Dr. Charles R. Robins writes under date of December 22, 1894, as follows: "I saw to-day the patient who was treated by you for femoral aneurysm about two months ago, and I am happy to be able to report that the clot which was formed under treatment still remains firm and solid, and has decreased somewhat in size. No pulsation in tibial or popliteal arteries, but the leg seems to be perfectly nourished."
SAWTELLE: FEMORAL ANEURYSM.

N. Y. MED. JOIR.

To afford the sufferer a better chance of recovery the removal of the limb was often the only expedient thought of for his relief. The operation of Antyllus was performed by Morel, of Paris, in the seventeenth century in a case of carotid aneurysm; by Keysiere, in 1744, in a case of popliteal aneurysm; and by Sabatier, not long afterward, in a case of femoral aneurysm. Mr. Syne employed it successfully in aneurysm of the common carotid, axillary, and iliac arteries, the first in 1857.

In 1710 Aneil devised and performed a new operation. He ligated the artery immediately above the tumor, but did not open the sac or tie below. The operation was successful, though the credit of presenting the new principle underlying this operation of ligating the artery on the cardiac side is given to John Hunter, who investigated the subject in 1785, and maintained that the cause of failure of Aneil’s method was that the artery was tied at a point where it was diseased, and hence the ligature came away too soon and secondary hemorrrhage was generally the result. He accordingly ligated the vessel at a point above the sac where it was healthy, and thus diminished the risk of hemorrhage. The death rate after ligature by the Hunterian method, according to Gross, is forty-one per cent. His table of six hundred and ninety-five cases, which included the large vessels, shows that two hundred and eighty-five died. In case of the femoral artery, the table gives two hundred and seventy-eight cases with a hundred and five deaths, a percentage of 37.76.

Braslor ligated on the distal side in case of aneurysms of the carotid, external iliac, etc.; and Wardrop tied the artery or one of its branches on the distal side of the sac. In the eighty-four cases reported, forty-two patients died. “The majority of the patients who recovered were greatly benefited, and in not a few life was prolonged for several years.”

It has been found that aneurysms have recovered spontaneously, as shown at post-mortems, the sac having in some instances pressed upon the artery and thus retarded or cut off the circulation. In other instances the sac has been found filled with a laminated clot where there appeared to be no evidence of pressure whatever.

Valsalva suggested for vessels inaccessible to the ligation or compression, treatment by absolute rest in bed with diet reduced to the minimum amount compatible with life, and an occasional venesection, together with the exhibition of certain drugs to control the circulation and favor coagulation. But this method has not been known to effect any cures.

Professor Tufnell’s modification of the above method consists in the use of three means—viz., rest, regimen, and medicinal agents. He demonstrated the powerful effect which the recumbent position has upon the force and frequency of the heart’s beat. He reduced the diet, but not to the verge of starvation, and thus secured a greater plasticity of the blood as well as diminished the action of the heart. Besides the remedies to induce sleep and control pain, he administered compound jalap powder at intervals to withdraw serum from the blood and favor coagulation.

Hey improved this treatment by substituting a saturated solution of magnesius sulphate for the jalap. Valsalva’s measures tended rather to increase the fluidity of the blood than otherwise. Under those of Tufnell it became more plastic. But to the strict recumbent position which he insisted upon is mainly due the large percentage of cures which he obtained. Of his ten patients, seven were cured and three died during treatment.

Instrumental compression has long been employed in many cases with varying results. Up to the time of Bellingham the results were anything but satisfactory. The instruments were generally clumsy contrivances, which hurt and injured the patients a great deal. The idea prevailed among practitioners that to be successful the instrument was to be applied firmly and steadily, so as to arrest the circulation and cause adhesion of the sides of the artery. One practitioner followed another blindly because it was occasionally successful in his hands, and not that any one had been so fortunate as to lay down broad and definite rules of action. It was for Bellingham in 1843 to point out upon correct and scientific principles that pressure should be exerted on the cardiac side of the tumor over a sound portion of the vessel. Thus was effected a complete revolution in the treatment of aneurysm, yielding results which are, says Gross, highly flattering, and contrasting most favorably with those of the Hunterian deligitation. There is but little if any danger from this mode of treatment, and in the event of failure more radical measures may be substituted.

Vanzetti first proposed digital compression in 1846, and a year later Professor Knight, of New Haven, cured a case of popliteal aneurysm in forty hours by this mode. Of a hundred and eighty-eight cases analyzed by Fischer there were a hundred and four recoveries, 75.3 per cent., with only one death caused by gangrene in a man seventy-one years old. Cure is obtained in a much shorter time by this method than by any other, except forced instrumental compression, the greatest objection to it being the difficulty in securing a sufficient number of assistants. Direct compression of the denuded artery was practiced during the close of the last and commencement of the present century by many Italian, French, and English surgeons. This consisted in exposing the artery and applying a temporary ligature over a cylinder of some suitable material and removing it after the sides of the artery were supposed to be fairly adherent to each other. This was occasionally followed by violent inflammation, secondary hemorrhage, and death. The operation, modified to lessen these dangers, is performed at the present time, but its value is undetermined. Forced compression with an elastic bandage, where the aneurysm was located in the extremities, has been recently tried. This acts to produce a complete stagnation of the blood in the limb by shutting off the collateral cir-

ANDERSON: ABNORMITIES OF THE NASAL SÆPTUM.

Feb. 23, 1895.

ABNORMITIES OF THE NASAL SÆPTUM
AND THEIR TREATMENT
IN THE CURE OF CATARRH.

By P. L. ANDERSON, M. D.,
CHICAGO

Sixty per cent. of all cases of nasal catarrh that the physician is called upon to treat are complicated by spurs, ledges, or deviations of the nasal sæptum. Our attention has not been particularly directed to these conditions, or to the important part which they play in the cause of nasal catarrh. We too often blindly follow a routine examination, and see only that which we have been taught to recognize as simply abnormal, overlooking apparently harmless deviations from the normal, because most textbooks mention them simply to dismiss the subject in as few words as possible. Until quite recently the medical profession has remained in ignorance of the presence and injurious influence of spurs and ledges of the sæptum, the impression prevailing that, short of noticeable obstruction, they were harmless ornaments, to be treasured as eccentric mural decorations of the great Artist who never created two things exactly alike. Much more attention has been given to the condition of the turbinated bodies than to the causes of their abnormalities. It has for ages been taken for granted that a dust laden atmosphere and certain climatic conditions are the primary causes of catarrh. If this is true, how can we account for the freedom from catarrh of the seventy-five per cent. of those who have healthy noses? Statistics show that one out of every four persons has catarrh. Climate seldom affects a nose having a normal sæptum. Relapse after treatment directed solely to the turbinites for the cure of nasal catarrh is of such frequent occurrence that many
physicians tell their patients that so long as they remain in certain climates there is no permanent cure to be derived from treatment, and advise them to take a change to a purer and a drier atmosphere. How many patients can and do follow this advice? Very few; they prefer to stay where prosperity has placed them, and, with the firm conviction that catarh can not be cured, are prepared to smile knowingly when told it is a disease which can be radically cured, but not on the old lines of treatment. Effects certainly should receive proper attention, but causes, which have received too little notice heretofore, should be removed to obtain a permanent normal condition.

The importance of recognizing the existence, the nature, and the results of these conditions leads us to the consideration of their pathology, diagnosis, and treatment.

In size, spurs and ledges of the septum vary from two to ten millimetres in width, and from five to seventy millimetres in length; they are usually irregular in shape, with one extremity broadened; thickened at their point of origin with the septum, and tapering to an edge at their distal extremity; covered with mucous membrane; and sometimes, though seldom, hypertrophied. They develop along the suture line of the cartilaginous septum and the spire of the superior maxillary, or at the suture of the latter with the vomer and the cartilage of the septum. Their material varies according to their position—cartilage in the anterior extremity, cartilage and bone in the middle, and bone in the posterior part. Their origin has not been satisfactorily explained. That they are congenital must certainly be accepted in a small percentage of cases; malnutrition may account for a few more; but in the great majority of cases traumatism plays an important part in their development.

Diagnosis.—They should be readily recognized by their cartilaginous or bony feel and immobility; by their relation to suture lines of the septum; by their spur, ridge, or ledgelike shape; by comparison with the opposite side of the septum, and by the more or less obstruction per se or which they cause by irritation of the opposing turbinate body by pressure or occasional contact. The ledge may lie so low down as to be mistaken for the floor of the nose.

The treatment is surgical: removal by the nasal saw or drill. Bone cutting forces are too bulky for the operation, obstructing the view of the surgeon. The cærsen would slip off, and for the same reason the galvano cautery snare would be useless and severe. The chisel is slow, and the field of operation is soon obscured by haemorrhage.

The enchondrotome removes but a narrow shaving at a time, and for this reason should not be considered. The dental drill is used mainly for the purpose of giving to the saw a starting point in cases where the obstruction is so great that the saw can not be safely introduced without it.

As the nasal saw is the instrument on which the success of the operation so much depends, it would not be out of place to consider the various points a saw should or should not have. It should be probe-pointed to avoid injury to the tissues posterior to the obstruction. The cutting surface of the blade should not extend more than thirty-five millimetres from its point, that injury to the tissues anterior to the obstruction may be avoided; the stroke of the nasal saw is necessarily short, and a longer cutting edge is superfluous. The teeth of the saw should not be so long or so coarse that they catch in the bony tissues and obstruct the free play of the saw, and the teeth should not be so fine that the saw will act more as a file than as a saw. From its probe point to the handle the blade should be of the length of the nasal cavity; if it is longer, with the necessary length of handle, it will strike the rhinoscopic mirror of the operator; if of shorter length, it will fail to reach the extreme posterior ledges. The blade should not be so thin and flexible that it leaves you in doubt as to the location and course of its distal extremity. You must know definitely where the point of your saw is traveling, otherwise it may take a circular course, and leave enough material for another operation. The blade should be as thin as is consistent with this requirement; in width it should be as narrow as the required strength will admit, so that its unnecessary size may not obstruct the view. The handle should be of such a size and shape that it may be firmly grasped by the thumb and the index and middle fingers, which gives much better control over its movements than when it is bent or curved at an angle to be held in the fist like a plow handle. A straight handle, of the shape and roughness of a three-sided file, eighty millimetres in length, each of its three sides ten millimetres in width, with one flat side uppermost, completes the description of a new nasal saw which I take great pleasure and no little pride in introducing to the

![Fig. 2.—(Half size.)](image-url)
medical profession as a saw designed from practical experience by the author.

Operation.—The parts should first be cleansed with an alkaline spray ("Dobell’s"), rendered thoroughly aseptic by a spray of bichloride (1 to 4,000), after which apply on a cotton tampon a ten-per-cent. solution of cocaine hydrochloride; the parts become anesthetized in from fifteen to twenty minutes. It is better to place the patient on the operating chair or table to avoid syncope, which sometimes occurs from the effects of the cocaine. With the head well steadied, the saw travels through the tissue in a few seconds. With narrow-bladed angular scissors clip the soft parts usually found attached to the lower side of the now severed bony part of the ledge, and with forceps remove the obstruction. Now apply on a cotton-keratinized peroxide of hydrogen, of full strength, to control the hemorrhage, which is often profuse, but never alarming, and under this application is checked immediately. Should it be necessary, on account of hemorrhage during any stage of the procedure, to obtain a clearer view of the field of operation, apply hydrogen peroxide, of full strength, to the cut surface, then gently remove with a cotton swab the foamy substance which is produced by the action of the hydrogen on the blood; the surface will now remain for some little time as free from hemorrhage as before the use of the saw. With a powder-insufflator project upon the cut surface finely powdered arista, which not only is an antiseptic of known value, but firmly adheres to the surface and prevents the constant oozing of blood and serum from the wound. Cleanse the parts daily for the next ten days with an alkaline spray ("Dobell’s"), followed by a spray of hydrogen peroxide, of half strength; then dress with arista powder. In a month or six weeks the exposed bone is fully covered with a new mucous membrane. Little or no reaction occurs as a result of the operation, and the patient does not lose a single day from his business in consequence.

A CASE OF MALARIAL HÆMATURIA,
WITH A STUDY OF THE PLASMODIUM.

By E. A. WOLDERT, Ph.G., M.D.,
FORMERLY RESIDENT PHYSICIAN, MERCY AND DOSELLA HOSPITALS,
PITTSBURGH, PA.

Mr. J. A. V., aged twenty-three years, was admitted into the St. Louis Southwestern Railway Hospital, December 6th. He was an American, a resident of Arkansas for the past five years, the latter two having been spent on the banks of the Red River. He suffered from chills and fever two years ago and again in July last year.

Present Illness.—On the night of December 1st he had a chill, followed by high fever the next morning, which continued constantly, always being at its fasting in the evening.

Five days later, while on the way to the hospital, he had another chill. His temperature on his entrance was about 102° in the morning and 103° in the evening. Next day, 101° in the morning and 102° in the evening. Third day, temperature in the morning was 100° and in the evening it was normal, where it has since remained.

Development of Hæmaturia.—On the morning of the fourth day of illness the urine first passed was tinged red; afterward the color became more pronounced, and was still present on the fifth day from the onset. The color was of a dark red and after the urine had stood four or five days a thick reddish conglomum appeared on the top.

Unfortunately, no microscopic examination was made.

Jaundice.—Severe icterus appeared on the fourth day of illness, and when he was admitted the whole body was of a uniform dark-yellowish color.

Blood Examination, December 8th.—A puncture was made on the end of the finger, and as the blood flowed out the color seemed to be more like that of reddish-colored serum and appeared to have an oily cast, indicating severe dyscrasia. Under the microscope extreme polikilocytosis was observed and all the corpuscles seemed deficient in coloring matter.

Those affected were in all stages of disintegration, some being represented by about a fourth of their normal outline with a concave border on the opposite side. In others one part of the globule preserved the normal shape, while on the other side only a rim of the cell could be seen, being partly detached at one extremity. Often the corpuscle appeared as if it had been split in two and the two portions with concave central borders stood opposite to one another.

The Parasite; ×580 (Leitz).—About one corpuscle in every fifty was affected. The parasites were seen both within and without the red cells. The intracorpuscular were of different sizes and shapes, the prevailing one probably having an almond outline with a hyaline or brownish color without pigment. It looked as if it had been stamped or cut out from the red cell, being in nearly every instance surrounded by a colorless rim. Often a portion of the protozoon would be partly extruded from the corpuscle. In some cases two haematozoa having the same shape occurred within the red disc. Some of the organisms were elongated, convex on one surface and concave on the other. Those parasites without the cells were also of different sizes and outline, some being round and hyaline, often not more than a tenth or a twentieth of the size of a normal red globule, while others were a fourth or even a half its size. Only in a few instances did the plasmodia have any pigment discernible. Perhaps the failure to observe pigment may be accounted for by the low power of the lens.

Free pigment was scattered throughout the field, often dark in color, while in others bright red masses were present. Many large lymphocytes were seen.

Stained specimens were unsatisfactory.

The blood was again examined December 18th, and the corpuscles had more of the normal appearance and only one organization was found. It was of a pear shape, hyaline or light brownish in color without pigment and very large.

Treatment.—Ten grains of quinine with a few drops of dilute nitrohydrochloric acid were given every four hours. Bowels kept open. Three days after cessation of fever five drops of Fowler’s solution were given three times a day.

Result.—The patient was discharged cured on December 21st.
AN OPERATION FOR RELIEVING PHIMOSIS WHEN COMPLICATING GONORRHEA, WITHOUT INFECTING THE WOUND.*

By R. M. Woodward, M.D.,
Passed Assistant Surgeon, U. S. Marine-Hospital Service;
Clinical Lecturer on Surgery, Medical Department, Western Reserve University, Cleveland, Ohio.

All general practitioners see many cases of gonorrhea, and among them is frequently one occurring in an individual the subject of more or less marked phimosis. The swelling of the glans penis and prepuce incident to gonorrhea increases the degree of phimosis. The pain produced by an attempt to retract the prepuce for purposes of cleanliness induces the patient to defer this act longer and longer, until finally it becomes nearly or quite impossible. Gonorrheal pus collects beneath the prepuce, especially back of the corona glandis. It can not be removed with a gonorrhoeal syringe.

The contact of the irritating pus soon causes balanitis and postitis, with gonorrhoeal ulcers, all of which complicate the original trouble, interfere with treatment, and make the patient miserable.

The usual treatment in such cases has been to slit up the back of the prepuce, and later on to circumcise, or to proceed to circumcision at once; but in either case the wound becomes infected, and an indolent ulcer the size of the entire incision results, which may last for weeks, and leaves an unsightly scar.

To relieve the constriction, and at the same time avoid infection of the wound, I adopted the following simple procedure, which, so far as I know, has not been suggested before:

1. Shave the pubes, penis, and scrotum.
2. Thoroughly scrub the parts with a solution of bichloride of mercury, 1 to 2,000.
3. Compress the glans penis, forcing the blood out, and dexterously slip back the prepuce over the corona glandis, converting the phimosis into a paraphimosis.
4. Cleanse the glans and prepuce well with the same antiseptic solution, and have an assistant hold the glans wrapped in cotton wet with bichloride.
5. Place a rubber band about the penis at the level of B, near the base.
6. Inject a four-per-cent. solution of cocaine subcutaneously, entering the needle just back of A and passing it down to and under the constriction at C, slowly injecting the solution during withdrawal.
7. Pick up the skin at A with two forceps, and snip with scissors.
8. Withdraw the foreskin to its fullest extent, bringing the constriction (junction of mucous and cutaneous surfaces) about a quarter or half an inch back of the corona glandis.
9. Introduce subcutaneously a grooved director at A, and pass down beneath the constriction.
10. Upon the director pass a tenotome flatwise, until the constriction is reached, then turn the cutting edge up, and gently sever the constricting band without cutting through the mucous membrane or skin.
11. Withdraw the instruments, remove the rubber band, check the few drops of blood that appear, take one or two fine catgut stitches in the wound, and close it with cotton and collodion, to prevent the absorption of any poison that may afterward touch it.
12. Lay one thickness of iodoform gauze over the glans, again compress it, and draw down the prepuce to its former position.

The operation in the prepuce is appreciably enlarged at the time, and this increases during the first three days. To prevent edema of the penis, bandage the organ snugly, swing the scrotum up over the abdomen, and give an opium pill the first two or three nights to prevent priapism.

The patient is now able to retract the prepuce at will, and daily dressings can be applied to the irritated membranes. The soreness disappears in a few days.

When the gonorrhoeal discharge has entirely ceased, circumcision can be performed if considered advisable; but in the cases where I have performed this operation, the opening in the prepuce has been rendered so large that there was no possibility of a phimosis occurring with any subsequent attack of gonorrhoea, and circumcision was not indicated. The operation is equally applicable to phimosis complicating chancroids. If the chancre should be in the dorsal median line beneath the prepuce, pass the grooved director and tenotome at one side.

The wound in the skin need only be large enough to admit the tip of a grooved director, and the resulting cicatrix is almost invisible. The tenotome should be well bellied and have a keen edge.

A Bureau of Autopsy.—In the year 1881 there was founded at Milan a unique and curious institution, which has been at work ever since. This was the Loria Bureau of Autopsy. It was founded, and placed under the direction of Professor A. Vergy, for the use of the inhabitants of Milan. That is to say, either courts of law or the family of a deceased person can have a complete examination and report in cases where a death has occurred under suspicious or strange circumstances. All autopsies are recorded, and may be consulted for purposes of study. The bureau is intended to serve two purposes—the advancement of knowledge, and to remove one objection to cremation raised on the grounds that crime may be less easy of detection when the deceased is effectually placed beyond the reach of examination.—Hospital.
A SUGGESTION AS TO THE TREATMENT OF PENETRATING WOUNDS OF THE CILIARY REGION AND LENS.

By ROBERT L. RANDOLPH, M.D.,
Baltimore.

Penetrating wounds of the ciliary region in the majority of cases lead to loss of sight. Such wounds then constitute the most dangerous injuries that can happen to the eye. Sympathetic ophthalmia usually has its origin in an injury of this character, and it is the fear of this termination that induces the surgeon to remove the injured eye at once. It has become indeed almost a habit to abandon hope as soon as we see an eye with a penetrating wound of the ciliary region and lens, and frequently no effort what ever is made to save the eye.

I am not in favor of temporizing with this class of cases, but it is certainly improper, to say the least, to take out the eye on general principles, and yet more than once I have seen an eye enucleated where the chances for sight were not absolutely gone, and where there was strong reason for not fearing sympathetic ophthalmia in the near future. Practically all wounds are infected. If not infected by the foreign body, they become so late on by the entrance into the eye of organisms through the passage made by the foreign body. There is no more favorable place in the eye for the lodgment and development of organisms than in the space between the iris and lens, and particularly in that part of the space where the ciliary processes project out. Here we find usually the point of injury, and from this point the microbes readily develop and can soon involve all parts of the eye. In many of these wounds the foreign body passes through into the lens, in which case the lens is penetrated by the aqueous humor, swells up, and becomes opaque; in other words, traumatic cataract forms. Of course, when the lens swells up it occupies more space than normally, and this means it exercises pressure in some direction, usually toward the wound, which further means that pressure is made upon the iris and ciliary body. At this latter point we have already an intense inflammation, and it is clear that every symptom of this inflammation will be made worse by the pressure of the swollen lens.

In the operation for soft cataract the great danger is this swelling up of the lens and the consequent pressure upon the iris and ciliary body, and so causing irido-cyclitis. It is possible in these cases that infection has also taken place; but it is unquestionably the fact that the swollen lens, if not entirely, is in great measure responsible for such an inflammation.

Now if under certain conditions with a normal iris and ciliary region the lens can do so much harm, how much more harm it can do when the iris and ciliary body are the seat of a traumatic inflammation. As is well known, soft cataracts are found in children, and it is important to remember that the older the patient the more apt is the lens to give trouble.

The points that I wish to bring out are—

1. The peculiar danger attending wounds of the ciliary region.

2. The tendency to adopt radical measures at once in dealing with these cases.

3. The fact that the crystalline lens often acts as a foreign body, and that its presence renders the condition of the eye more dangerous.

The truth of these propositions is illustrated by the following histories:

A man, thirty years old, was struck in the left eye by a small particle of steel. He was a mechanic in the Baltimore and Ohio Railroad shops at Glenwood, Pa., and not far from Pittsburgh. He went at once to a well-known oculist in the latter city and was told that the eye should be removed immediately, and was given to understand that there was nothing further to be done. He refused to submit to an operation until he had consulted another surgeon. I saw him on the third day after the injury. There was a small wound a little above and to the nasal side of the cornea. The wound started at about a quarter of an inch from the corneo-scleral junction and passed outward into the cornea for an eighth of an inch. The iris was prolapsed at this point and the lens was opaque and bulging forward. He had been using atropine and the pupil was partially dilated. He did not recognize light promptly, though light perception was present. The tension was somewhat lowered, and the eye was sensitive to the touch. At the point of injury the posterior chamber was obliterated, but below there was still a space between the lens and iris. It was a typical picture of irido-cyclitis. He was willing to have anything done but enucleation, and only one alternative occurred to me, and that was to enlarge the wound, cut off the prolapsed iris and deliver the lens, and endeavor to push out the inflammatory products at the site of the injury. This was done after first sterilizing the instruments. I found no trouble whatever in getting out the lens, and I got a perfectly black, clear pupil. After the operation atropine was instilled and a pressure bandage was applied, and two weeks later he was able to count my fingers a foot from his face. All acute symptoms had passed away and he had had no pain since the operation. When I last heard from him he could tell a man from a woman across the room. This was the last I ever heard of him, and I am unable to say what vision he has at present.

The second case was that of a track foreman, aged fifty years. He was also from Glenwood. He had received a penetrating wound of the ciliary region of the left eye. The foreign body was a piece of steel and had entered the eye from the temporal side, making a wound about a quarter of an inch long into which the iris prolapsed. He said that a friend had extracted the piece of steel as it was sticking out of the wound. He had also gone immediately to Pittsburgh and consulted an oculist, and, just as in the first case, this oculist advised the removal of the eye, and told the man of the danger of delaying the operation. The idea of such an operation, however, frightened him away, and he came to see me the next day. The entire lens looked as though it were opaque, though there was no external evidence of pressure from this source. The eyeball was sensitive to the touch and was much inflamed. Hypopyon was present to a slight extent. I agreed with the oculist in Pittsburgh, and said that the eye ought to come out at once. I may add that he had light perception and that was all. He could not bear the light on the eye, and was troubled with distressing photophobia in the other eye. I tried to persuade him to submit to enucleation, as I was quite certain that he would never see again with that eye. He positively refused to have the eye removed. I thought I would attempt the removal of the lens simply as an experiment, though I had no idea that it would do any good. The wound was located below and to the temporal
side of the cornea and passed up along the latter. I enlarged
the wound to twice its original size, performed an iridectomy,
and pressed out as much of the lens as possible. I am sure I
failed to deliver the whole lens, but I got most of it out, and at
the same time I pressed out the pus in the anterior chamber.
The operation was a very painful one, owing to the congestion
and consequent failure of the cocaine to act. Immediately after
the operation he could see my hand passed in front of his face, but
could not count the number of fingers held up. A compress
bandage was applied and atropine was ordered to be dropped in
the eye every three hours. After the first day he had no more
pain, and in two weeks he counted the number of fingers held
up six inches from his face. I saw him again two weeks after
this, but there was no further improvement. The eye had lost
all signs of irritation.

In both these cases after removal of the lens the ophthalmos-
scope revealed large opacities in the vitreous body, which no
doubt were the results of hemorrhages. I think it highly prob-
able that the vision still further improved with the clearing up
of those opacities, though it is unlikely that good sight was or
ever could have been obtained.

The third case was that of a boy ten years of age who, in
trying to pull a pen out of the penholder, had run the pen into
his left eye. He had put the penholder under the desk lid and
notied a companion to sit on the lid while he knelt on the floor
and pulled at the pen. The penholder slipped from under the
lid and, as I have said, pierced his left eye. The wound was a
small one, and was at the corneo-scleral junction and just at the
top of the cornea. The iris was torn from its ciliary border,
the capsule of the lens was ruptured, and traumatic cataract was
present, the anterior chamber being partly filled with cortical
matter. The wound had been received four days previously.
The eye was very painful and the boy could not face the light.
It could be easily seen that the lens was acting as a foreign
body and I determined to remove it. He was chloroformed, and
I enlarged the wound in the cornea, cut out a small piece of
the iris, and without any difficulty pressed out the soft cortical
substance. The eye made a rapid recovery and the boy now
sees quite well. It is more than probable that the removal of
the lens would have suggested itself here to any one as the
most sensible course to follow, but the difference between this
case and the first two was not a wide one, and if left to itself
much longer there was scarcely a doubt but that the inflamma-
tion would have become worse and sight would have been ulti-
mately lost.

It will be seen from this that in two cases where it is
usually thought necessary to enucleate the eye, the removal of
the lens was followed by recovery. When I say recov-
ery, I do not mean that such an eye has the possibilities
of an eye after an uncomplicated cataract extraction. In
both cases—in fact, in all three—the retina had undoubt-
edly suffered permanent injury, and while all the evidences
of an acute inflammation had passed away, it is certain
that vision had suffered considerable loss. Just how much
vision was preserved could only be determined after the
lapse of several weeks when the opacities in the vitreous
body had been absorbed. The vision, though that was
present two weeks after the operation, undoubtedly justified
the operation, and it is reasonable to think that in similar
cases the removal of the lens will sometimes do away with
the necessity of enucleation and leave the eye with some
vision.

It should be remembered that in this class of cases
there is generally only one thing done, and that is enu-
cleation, and the reason why we usually follow this course is
the fear of an outbreak of sympathetic opthalmia.

Now, this disease rarely, if ever, shows itself for at least
three weeks after the injury, and usually at a much later
period; and again it should be remembered that sympa-
thetic opthalmia is a very remote contingency, and, while
it should ever be had in mind as a possibility, it should
not, in my opinion, determine us to take out an eye in the
first week after the injury unless the eyeball is soft and
there is a protrusion of the vitreous body and a large cor-
neal wound. If much of the cornea is cut off from its
source of nutrition it is rarely able to withstand the attack
of organisms and almost always sloughs, and in those cases
where the wound extends clear across the cornea we fre-
quently have panophthalmitis.

The cases that are particularly well adapted to this
method of treatment are those where the wound is small
and located at the corneal-scleral junction, and where it is
not only easy to enlarge the wound, but it presents the
most natural point for the egress of the lens. The time to
operate is as soon as we see the patient. Waiting for fur-
ther developments means ultimately enucleation. The
longer we wait the more complete become the adhesions
between the anterior capsule and the iris. An exudate
spreads itself out over the posterior surface of the iris, the
capsule of the lens, and ciliary processes, and later on this
exudate is replaced by a membrane that serves to enfold
totally this part of the eye and transform it ultimately
into a mass of disorganized tissue. In this stage it is
almost impossible to remove the lens and even difficult to
perform an iridectomy. I have a number of times enu-
clated such eyes months after the injury, and on cutting
open the eye and separating the parts have been struck by
the condition of the ciliary region. It is generally impos-
sible to separate the mass at this point without tearing it
tall to pieces. When the operation is done before the ex-
udate has become organized, the iris can readily be drawn
out and the lens delivered with comparative ease.

Conclusions.—1. In penetrating wounds of the ciliary
region and lens, even where light perception is gone, and
where usually enucleation is performed, the removal of
the lens will often be followed by the recovery of comparatively
useful vision.

2. The time to perform the extraction is in the first
week of the injury, when there is less reason for entailing
the fear of sympathetic opthalmia, and that sympa-
thetic disease is too remote a contingency in any event,
and certainly at this stage, to outweigh every other con-
sideration.

3. The effect of the operation is to remove what is
really a foreign body, and at the same time it frees the
ciliary region of its infectious contents—very much the
effect of opening an abscess.

4. Cleanliness is imperative in this operation. I usually
sterilize my instruments in a two per-cent. solution of bicar-
bonate of sodium, and keep the field of operation constantly
irrigated with a two per-cent. solution of boric acid.

Any solutions that irritate—such, for instance, as sublimate
solutions—are to be avoided, as they weaken the resisting powers of the eye. The after-treatment consists in the installation of atropine, one per cent., every four hours, and the wearing of a compress bandage.

5. Improvement in these cases, as would be expected, is rapid, and unless it is rapid one should not delay evacuation.

ON A LOCAL VASCULAR DISTURBANCE OF THE FETUS, PROBABLY DUE TO THE INJECTION OF TUBERCULIN IN THE PREGNANT COW.

By THEOBALD SMITH, M. D.

(From the Pathological Laboratory of the Bureau of Animal Industry of the United States Department of Agriculture.)

The two following interesting cases are published not for the purpose of formulating any new hypothesis concerning the relationship existing between the maternal organism and that of the fetus in utero, but to stimulate others to search for similar cases. The number of cattle killed after a positive tuberculin reaction is at the present time by no means insignificant, and if careful examination be made of the uterus in every animal we may expect more illustrations of the striking condition to be described.

Case I.—A Jersey cow, four years old, received an injection of tuberculin April 17, 1894, and gave a well-marked reaction on the following day.* The injection was repeated April 27th, but a maximum elevation in temperature of only 2° F. was noted on the following day.

On May 7th a third injection was made, and a short but well-marked rise to 105° 8′ was noticed on the following day.

On May 8th five times the usual dose was injected: one half in the region of the neck, the other half in the region of the shoulder. Only a very slight elevation was noticed. Unfortunately, the notes do not state on which side these injections were made. It is highly probable, however, that the three last injections were distributed over both sides of the neck, as this is customary when injections are made in close succession.

The cow was killed May 10th by a blow on the head and by cutting the vessels of the neck.

The following is an abstract of the notes dictated by the writer at the autopsy:

Animal about four years old, in rather thin condition.

At the seat of the first injection (May 7th) a small amount of blood extravasation. At the seat of one of the second injections ecchymosis with vascular dilatation in the subcutis over an area three inches in diameter. Induration and pale discoloration of the subjacent muscular tissue over an area two inches by one.

The tuberculous lesions are distributed as follows:

Right retropharyngeal gland of from three to four times the normal size. Contains many yellowish, cheesy foci of irregular outline.

The tonsils and other glands of the head normal.

In the left bronchial gland, two necrotic, still firm foci, each about a quarter of an inch in diameter. No other tuberculous lesions in the thorax.

Several abscesses embedded in neoplastic tissue which binds

---

* These tuberculin tests were made by F. E. Kilborne, B. V. S., to whom I am indebted for the notes on that part of the work.
due to a piece of wire. Two similar abscesses in the liver probably secondary to the traumatic infection.

The fetus was seventy millimetres long from the vertex to the root of the tail. In front of the left shoulder there was plainly visible a blood-red spot suggesting subcutaneous hemorrhage. There was no surrounding network of injected vessels as in the case of the two fetuses described above, nor was there any indication of vascular disturbance on the opposite side. The blood-red spot was situated directly in front (cephalad) of the scapula and slightly above (dorsal of) the level of the shoulder joint. Its dorso-ventral diameter was about eight millimetres, the one at right angles to it (cephalo-caudal) about four millimetres. The spot was thus oval in outline.

One of the twins of the first case was hardened in Müller's fluid and alcohol, and the injection was by this means very perfectly preserved. In the fetus of the second case the same process of hardening was not so successful, probably because of the existence of a denser skin. The intensely red spot in the fresh embryo has given way to a dull spot not noticeable unless attention is specially called to it.

The nature and exact seat of the lesion has not yet been investigated. The writer hopes soon to make transverse sections in order to locate and define more accurately the appearances described.

If we briefly summarize the facts presented we note that in one animal having received two injections of tuberculin on consecutive days, probably on different sides of the neck, twin fetuses showed hemorrhage associated with vascular injection having its focal point at a place corresponding to the seat of injection in the mother. In one fetus both sides were involved; in the other, only the left. In the second case the injection was made only on the left side, and the fetus examined four days and a half later showed a distinct blood red, probably hemorrhagic, spot at the corresponding region.

A small number of fetuses of more advanced age and several of nearly the same age have been examined since, but no lesions of the kind have been found. It is probable that we must realize a definite combination of certain conditions before this remarkable effect may be actually seen. These are a certain age-limit of the fetus, a certain time-limit between the tuberculin injection and the autopsy, and perhaps a certain improbable condition of the mother. The disturbance being vascular, the lesions noticed may in course of time entirely disappear.

THE DISPENSARY EVIL.*

By FERD. C. VALENTINE, M. D.

Much has been recently said regarding the monetary injury done the medical profession by charitable institutions, and particularly by dispensaries. There is sufficient basis for these complaints to warrant serious consideration. Unfortunately, adequate presentation of the fact is beyond my weak powers, and almost impossible within the ten minutes your by-laws prescribe as the time limitation for papers read.

There can be no doubt that dispensaries are frightfully abused. Scoundrels who can pay well for professional services come to dispensaries to steal services and medicines and appliances. How often this happens is well shown by the books of the West Side German Dispensary. There, more than in the records of any other charitable institution, we find the entry: "Refused to treat him (or her) because of ability to pay." Much of the credit thereof you will certainly give to me. Every incumbent of a class and every assistant will remember that during the nearly two years in which I have had the honor to be this medical board's president I instructed each one to exercise the utmost vigilance in this regard. I have gone so far, even, as to warn every one that I would apply for his dismissal if he knowingly gave to unworthy people the services which rightfully belong to the poor.

That such a course is correct no one can deny. If our services were given indiscriminately, incalculable injury would be done the profession, and especially its younger members. And the deserving poor would be equally hurt thereby.

Much of the damage done the profession has been felt since November, 1893. On the 6th of that month this dispensary was opened in its new building, at 328 West Forty-second Street, to a wider activity than could have been possible in its obscure little house on West Thirty-eighth Street. The dates came closely together. It is to be regretted that some men associate one with the other.

But is it not a fact that the general financial and business depression, which threw upward of a hundred thousand people out of employment in New York city alone, began to be most keenly felt from October or November, 1893! Is it not equally true that, thanks to the efforts of the medical profession, sanitation, sanitary education, and public precautions have since then begun to bear their fruits? Do we not daily read in the medical journals of the very small amount of illness throughout the world?

Therefore it can not be held that the West Side German Dispensary has had anything at all to do with the reduction of practice.

But it does not stand alone under the charge of augmenting the dispensary evil. All institutions founded and conducted by charitable people directly or indirectly contribute to it. Should, therefore, all such institutions be abolished? A few may possibly steal those services and medicines which belong to the poor. Should, therefore, worthy sufferers be allowed to die, to leave children to increase the ranks of the deprived and the criminals? A man unable to work because of illness can not prevent his children's need for food. They will not starve; therefore it is necessary for public weal that the bread-winner recover, lest his children prostitute themselves or become thieves for sustenance.

Many reasons, and all of them self-evident, could be adduced for the existence of public and private charities.
The injury done by them to those who suffer losses thereby can, in my opinion, be minimized, but never entirely cured.

Our profession, beyond all others, is the least amenable to the relief from imposition. The very character of our vocation inhibits this. No one enters the practice of medicine with the intention of earning more than, at best, a fairly decent livelihood. If he does, he will soon discover his mistake.

Then, looking about for the cause of his disappointment, he falls upon the thousands of people to whom the services he would sell are given gratuitously at the dispensaries. To this he hastily attributes his exchequer’s ebb. He forgets that to render the best possible services he must annually spend a fortune in new books, instruments, and appliances. He forgets also that many medical men who enjoyed the reputation of earning fortunes were buried by the charitable contributions of their colleagues.

Then, again, does not every one daily give away his services without even a thought of reward? To demonstrate this assertion, let me cite a small instance.

You are riding in an elevated train. Opposite you sits a woman whose garb, whose jewels, proclaim her to be of the wealthy class. At her side is a little child; its manner, its prattle, can not but attract your attention. The child asks its mother a question and looks up for her reply. A train dashes by over the opposite track. Bits of steel are ground from the rails and the wind whirs them through the open window. The child utters a cry of pain and plunges its little gloved hand into its eye.

As unconsciously as you respire, you have leaped from your seat, have deftly turned the child’s lid, removed the steel before it penetrated the cornea, and returned to your place, not even thinking of the eye you have saved.

Only this moment do you attempt to recall how many times you have done such a humanitarian, such a purely charitable act. Would a fee of ten dollars not be insignificant for the service?

Now, considering that the elevated roads in this city carry six hundred thousand passengers daily, would it be excessive to estimate that one in each one hundred thousand suffers the accident and is relieved without paying a fee for it? That would represent six daily—two thousand one hundred and ninety in a year.

Thus, by yielding to the promptings of the most ordinary humanitarianism, the profession loses just twenty-one thousand nine hundred dollars every twelvemonth, and would one of those thus receiving gratuitous services willingly lose an eye for ten dollars? Certainly not one.

Would you, because the profession thereby loses money, let a fellow creature continue to suffer and take the chance of becoming blind? Whatever motives may underlie this whole matter, the most sordid of medical men would not commit such a crime. Thank God for it!

But, not only in removing foreign bodies from the eye, for which you do not expect even thanks, do you daily, hourly toil, slave, struggle. Our is the only vocation which continually labors against its own interests. Do you not study, write, and speak in public, teaching how to prevent the very diseases that give you your bread?

Did not Jenner show how small-pox would be eventually stamped out?

Did not Koch struggle to combat phthisis?

Did not Pasteur lead on to the road which will eventually render the rabid dog’s bite innocuous?

Are we not all laboring to-day that diphtheria, the most profitable of all diseases, shall cease to exist?

But why repeat examples?

Our profession is a priesthood—one without which no other could exist. By striving for corpus sanum in publico, we make place for menus sana.

Not one of you will rise when I ask for him who will not do his utmost to prevent disease. No, not one.

I have shown you that twenty-one thousand nine hundred dollars are lost to the profession annually in this city by a very small matter. Who will estimate the millions of dollars you every year leave in pockets where they do not rightfully belong? A small fraction of this sum would sustain every dispensary in the United States.

But let us revert to the subject of this paper.

Many dispensaries are open to the poor in the evenings.

It is said that those evening classes are of greater financial injury than all others to the profession. It is alleged that mainly those who have followed her “whose feet take hold on hell” are treated in the evenings. And it is held that those who come at night work during the day, earn money, and consequently can pay for professional services.

At a first glance all these propositions appear correct. But can we ever be satisfied with our first impressions?

The prime postulate, that the evening classes are of greater monetary injury to the profession, will be quickly swept away in considering the others.

It is perfectly true that the majority of cases which visit the evening classes are attended to in my department. Equally true it is that the majority of those are ill because there is no sanitary law calculated to prevent venereal diseases.

This is neither the time nor place to discuss whether those who suffer in consequence of their own acts merit the punishment. In my humble opinion, he or she who contracts any of the diseases pertaining to my specialty did so in yielding to the most powerful impulse of human or animal nature. Those who condemn arrogate to themselves greater wisdom than God possesses. It sounds very pretty to urge purity upon men—and some women.

Those who understand French would reply: “C’est plus fort que moi.”

Whether they should be condemned or not, is beyond the pale of the present discussion. The fact is, that they of whom we speak have acquired diseases which, if not treated, will incapacitate them for work. They will make them inmates of hospitals and thus charges upon the community, or, worse still, will make them progenitors of tainted issue to increase the ranks of panners and criminals.

It would be sad if, knowing these things, we did not treat such patients anywhere and everywhere. We can not
assist in averting national calamities presaged twenty centuries ago. Even then syphilis was spoken of as a disease which affected unto the third and fourth generations.

But, as you quite correctly hold, physicians must live; and the more money they earn, the more can they spend for the benefit of suffering humanity. It is equally true that no class of patients are less grateful than those who have fallen ill in consequence of giving loose rein to the genesic impulse.

Physicians would be more than human if they did not expect a slight increase upon the ordinary fee for such services. It is a curious fact that they are obliged to collect their fees in advance. If they fail therein they will be but rarely compensated in their work.

Equally so, it is not surprising that some dispensaries refuse to treat these cases.

But, despite the origin of these diseases, despite the notorious ungratefulness of these patients, despite the example set by the institutions mentioned, a study of these diseases and their consequences can not prevent one from sympathizing as keenly with those who suffer from them as with people who have acquired illnesses in any other manner.

But I must ask you to inquire more deeply into the question. Men go to the dispensary while earning seven dollars a week—say thirty dollars a month. Out of this they pay eight dollars rent a month; with the remaining twenty-two dollars they feed and clothe a wife and six children. If they take half a day off to seek help at a dispensary during the day they are likely to lose their situations. Is it not better that while such a man is ill he go to the dispensary in the evening rather than that eight people, because of his small ailment, become charges upon the community?

A boy earning three dollars a week, through his own fault or not, contracts urethritis. Can he pay from the earnings which he contributes, perhaps, to an invalid widowed mother's support?

Many laborers, male and female, must struggle in the carpet factories from early till late for the pittance to keep body and soul together. Shall we refuse to treat their varicose ulcers in the evening because they are earning a few pittance cents during the day? These examples could be multiplied interminably. You know their force.

But the fact remains that public and private charities are frightfully, shamelessly abused. Thought and study suggest to me a remedy which, though by no means perfect, may prevent much of this abuse.

It rests in organization. Let a dispensary society be formed. The incumbents of dispensary classes, about six hundred in New York, and their assistants, about twelve hundred in number, should contribute to its support. Let the chiefs of classes pay one dollar monthly to the society, and the assistants twenty-five cents monthly. This would give a monthly revenue to the society of one thousand dollars. From this fund let each dispensary be provided with a photographic camera and supplies sufficient to reproduce the features of each applicant who may reason-

ably be open to suspicion of having no claim on the dispensary's charity. It will be an easy matter to get such an applicant into a room set aside for photographic purposes and question him as to his name, residence, age, social condition, and everything else that may lead to his identification. All these facts may be entered upon printed blanks kept for that purpose. These, with the photographs attached, are given to inspectors paid out of the society's funds. They investigate at the residence given each case during the same day and indorse upon the blank what they ascertain. If the applicant is found not to be entitled to charity his picture is multiplied and the facts on the blank are reproduced in sufficient quantity to cover all the charitable institutions in the city, to each of which a photograph with information is confidentially sent the following morning. These then, knowing the facts, can act in concert with other dispensaries in protecting the worthy poor and the medical profession.

Thus have I crudely set before you a suggestion of a remedy for the dispensary evil. May it be the basis for a discussion which will lead to improvement of the idea or the establishment of a better plan.

MICROSCOPICAL REMINISCENCES.*

By PALMER C. COLE, A. M., M. D.

It was my good fortune to be a student of the Harvard Medical School when Oliver Wendell Holmes was professor of anatomy and physiology. Professor Holmes was an enthusiast in the use of the microscope, and possessed some of the finest of the Spencer lenses, then the best in the world. He had constructed a stand, principally of wood, stable enough to allow the use of high-power objectives, and so simple that any student with the slightest mechanical ability could make one for himself. My first stand I made on this model at a cost of about fifty cents for material.

The coarse adjustment was obtained by means of a pin in the tube carrying objective and eyepiece, which was pushed against a wedge-shaped piece of brass. The fine adjustment was obtained by revolving the pin against the wedge. Over the tube was slipped a cardboard disc, some six to eight inches in diameter, covered with black velvet, allowing both eyes to be kept open during observation. The tube was also lined with black velvet. The tube support revolved on a pivot allowing inclination, though we were taught to use it with direct light. In a recent letter to me, Oliver Wendell Holmes refers to this stand as "a rough wooden contrivance that answered its purpose." Later, Holmes's lecture-room microscope, for use in his own class, became very popular, and is still extensively used.

Notwithstanding his engagements with others in founding the Atlantic Monthly, his medical lectures five days a week, an occasional public lecture, and monthly installments in the Atlantic of that brilliant series of essays,

* A portion of a paper read before the Northwestern Medical and Surgical Society, October 17, 1894.
The Autocrat of the Breakfast Table, he found time at his own house in Montgomery Place to give weekly instruction to half a dozen chosen students in the use of the microscope. In 1856 and 1857 I was fortunate enough to be one of the chosen half dozen. We were taught the use of the instrument and the preparation of slides. The slides used from week to week were prepared by Holmes himself to show the different tissues of the body.

The only consideration ever given for these charming and instructive lessons were the grateful thanks of his pupils.

I believe that Oliver Wendell Holmes was the first in America to teach classes of medical students the use of the microscope. If so, to him, and through him to the Harvard Medical School, should be accorded the honor.

Since writing the above Oliver Wendell Holmes has passed away. None knew him but to love him. His anatomical and physiological lectures were charming and always filled the amphitheatre; even dry bones in his hands became endowed with life and individuality.

It was my rare good fortune to be occasionally invited to his house, where I spent some delightful hours in his study and workroom. Once I was present when a large package of books arrived from New York for his inspection, which I helped him unpack.

When at the bottom of the case we came upon a large folio copy, original edition, of Vellins, his eyes fairly sparkled with joy. Hastily he turned over the leaves and remarked that, as New Yorkers had been fools enough to allow such a prize to leave their city, it would never return from Boston.

All the world knew him as professor, author, and poet, but few knew his fondness for music, and that he possessed a rare mechanical genius of which he was very proud. He once told me he thought more of the "gimcracks" he made with his hands than of anything he had ever written; and at that time he was delighting two hemispheres with The Autocrat of the Breakfast Table.

In his last autograph letter to me he says: "My most successful contrivance was a stereopticon of a very simple pattern, which had a great run, and has remained popular, I think, to the present time."

The last time I was in Boston, a few years ago, I met Holmes by chance at the corner of Charles and Beacon Streets. After a short conversation he invited me to call on him that evening between seven and eight, an invitation I gladly accepted. Holmes was alone, and I passed one of the most delightful evenings of my life. Though I should have preferred to listen, I was obliged to keep up my share of the conversation. Though The Autocrat in print, he was anything but that in private. He had the rare power of drawing the best thoughts from those with whom he was conversing. I have seen him hold a circle of a dozen men in conversation, and such was his tact that every man went away thoroughly satisfied with himself and delighted with his host. For myself, I have never left his presence without feeling that I was better intellectually and morally for the association. About half-past nine my evening came to an end, as Holmes was obliged to leave to attend a large reception. It was the last time I ever saw him, and I love to think of him as he looked when he bade me good-by.

It has given me great pleasure to be able to add this simple tribute to the memory of Oliver Wendell Holmes.

One of the most genial, accomplished, and talented men America has ever produced has passed from our midst. Peace to his ashes.

When I commenced my medical studies the professional use of the microscope was principally confined to examination of the urine and tumors. To-day it would be difficult to tell in what disease it is not used as an assistance to a correct diagnosis, or to detect the insidious invasion of some complication.

With the brilliant demonstration by Pasteur that there was no spontaneous generation, but that all the lowest forms of life arose from living germs with which the atmosphere was crowded, and when those germs were excluded all remained sterile—his discovery of the phylloxera, his discovery of the bacilli of anthrax, and the means of rendering cattle immune—a new field was opened.

Lister, with rare sagacity, applied these investigations to the treatment of wounds, and antiseptic surgery was born, with what benefit to humanity you all know.

Koch and his school started investigating the microbe causes of disease, followed by European and American investigators, and bacteriological studies, still in their infancy, have become indispensable.

In many of our hospitals, and with some private practitioners, it has become a routine duty to examine the urine and spuata of all patients.

The vomitus and dejecta are both examined; all the secretions—even external. To the dermatologist the microscope is indispensable.

In pernicious anemia we count with care the comparative number of the red and white corpuscles, and obtain a certain knowledge of the effect of our treatment.

In suspected cases of malarial complication we examine the blood anxiously for the malarial bacillus, or those queer Brownian bodies sometimes found in the red corpuscles.

The specific germs of a large number of diseases have been determined.

Unfortunately, this knowledge has been so far but of little use in the treatment of many diseases. The great vitality of the germs, their almost incredible powers of increase, have set at naught our boasted science.

Nevertheless, we can point with pride to what we have already achieved. The discovery of the tubercle bacillus as the cause of consumption has already saved a large number of lives. It has caused us to take prophylactic measures of great value, and, in spite of the lamentable failure of Koch's lymph, measures already inaugurated will save innumerable lives in the future.

If we may believe the reports from India, the mortality from cholera has been greatly reduced, with the prospect that, working on the same lines, inoculation with attenuated virus, a prophylactic or specific to the disease may yet be found.

In diphtheria, that most dreaded and fatal of infantile diseases, we have in the antitoxine solution of Dr. Roux, of
Paris, a student of and collaborator with Pasteur, a prophylactic, and after the disease has been contracted almost a specific if used in the earliest stages.

In the Trouseau Hospital at Paris, where the antitoxins, or, more properly speaking, the antidiaphtheritic serum, has been given a fair trial, the mortality has fallen from sixty-three to twenty four per cent., though many of the patients were brought in in the advanced stage of the disease. In the hospital of the Enfants malades, under the personal supervision of Dr. Roux, the mortality has fallen to eleven per cent. In hospitals where the old treatment was followed we have the old results—a mortality of from fifty to seventy per cent.

The number of cases so far reported is conclusive as to the great value of this remedy.

Unfortunately, it is expensive. Our board of health have applied for a small appropriation to enable them to produce it for the use of the poor. This appropriation should be granted immediately. It should be increased tenfold to enable every practitioner in New York to obtain a supply at cost price.

The solution is stable and can be kept for a year without losing its efficiency. The serum dried in vacuum is also stable and readily transmitted by mail.

Encouraged by past achievements I see no reason to doubt that in the near future we shall discover a prophylactic or specific for at least all contagious diseases.

Prophylaxis rather than cure has been as yet the result achieved, and, after all, the old adage holds true, "An ounce of prevention is worth a pound of cure."

While these great advancements were taking place, methods of investigation changed. Freehand sectioning and teasing tissues with needles gave way to the use of the modern microtome, by means of which we can obtain uniform sections of any desired thickness, and, if we wish, mount a whole specimen in serial sections.

Chemistry was called in to render its aid; various staining media were used for the purpose of differentiation of tissues and determining the species of bacilli and micrococci. To enumerate the different processes would require a small volume.

While histologist and bacteriologist were making such marvelous advances, opticians were not idle. Through their efforts have scientists been furnished with lenses fitted for their use.

Spurred on by rivalry and the demands of amateurs for wider angles to resolve the difficult lines and finally the dots or so-called pearls of the diatoms, each maker succeeded in improving his lenses. As the demand increased, so did the number of manufacturing opticians.

The brothers Grunow, then, in New Haven, Conn., afterward of New York, made stands and objectives especially designed for physicians and admirably adapted for their use.

Alvan Clark began life as a gun-maker; made the old fashioned target rifles, dear to the hearts of the sportsmen of the time; took them to target and turkey shoots, proved their superiority, and sold them. Becoming dissatisfied with this business, he abandoned it, and turned his attention to portrait painting, in which he was making a great reputation as an artist when he wanted a microscope and made one for his own use. After this he abandoned portrait painting and turned his attention to the construction of telescope lenses. Owing to this happy diversion of his genius America has the honor of having produced the largest and most perfect lenses for astronomical purposes the world has ever seen.

Had the bent of his genius turned to microscopy instead of astronomy we can only conjecture what the result might have been, for his first and only objective, a quarter inch, gave excellent results on the pygidium of the flea and seizes of insects.

I had the pleasure of using this microscope in the late Alvan Clark's house in Cambridge.

Alvan Clark was forty years old when he ground his first lens. Many a night have I spent with him in the rear basement or cellar of his house when he was engaged in grinding and polishing large telescopic objectives.

The trunk of a tree deeply imbedded in the earth passed through a hole in the floor and supported the "tool" in which the lens was ground. Here, seated on a triangular footstool, he passed days, weeks, and months in solitary and arduous labor. It was necessary to keep both glass and tool moistened with water while working. When the time came for the final polishing and shaping of the lens, to rectify by the most delicate manipulation the slightest defect in curvature, the work could only be done on a clear starlight night, when from time to time the lens was taken out into the open air, placed in its supports, and tested time and time again, until its resolution was as perfect as human skill could accomplish.

Then came my reward, as Clark was pleased to show me some of the most wonderful things in the heavens—double and triple stars—and never since have I had the pleasure of looking through a first-class telescope.

From Alvan Clark I received my first instructions in grinding and polishing glass.

Robert Tolles, who had been with Spencer, left his workshop and established himself in Boston.

The battle between low and wide angles was on. Most histologists were satisfied with low angular aperture, saying that it gave them greater penetration. Students of diatoms demanded the widest obtainable angle, as by wide-angled objectives only was they enabled to resolve the beautiful lines on the frustules of diatoms, which were their favorite study.

I have in my possession a fine one-fifth-inch made by William Wales, of Fort Lee, New Jersey, which has two back systems of lenses, interchangeable, one to give low, the other high angle. The objective was an expensive one, the idea patented, but no optician would make such an objective to-day.

The discussion is happily ended. To-day histologists and bacteriologists use the widest angled lenses, they can obtain. By their aid only has the science of bacteriology been enabled to make such giant strides.

First, dry lenses only were made; then came water and glycerin immersion, then oil and homogeneous objectives.
To America is due the credit of this last great advance, for the first homogeneous immersion objective was made by Robert Tolles, of Boston, for the United States Army Medical Museum, Washington, D. C. It was used by Dr. Woodward, United States Army; the immersion fluid, Canada balsam. The objective is the property of the United States Government.

With wider angles more light was required, and we were supplied with achromatic condensers, and later with wide-angled condensers which admitted of the use of immersion fluids.

There was but one more step to be taken, and the liberality of the German Government supplied the means for investigation which enabled Abbé and Zeiss to give us the apochromatic.

The last production of Zeiss, with the enormous N. A. of 1/63, has in the opinion of Dr. Henry van Heurck reached the limit of possibility.

The great primary cost of this objective, and the skill requisite to use it, place it beyond the reach of most.

The objective costs three hundred and twenty dollars; it is difficult to handle, and requires, to show all its capabilities, flat-glass slips costing eighty cents, flat-glass cover glasses costing forty cents, both easily broken; a condenser with flat-glass front, all of at least 1/6 refractive index. The object, condenser, and objective all to be immersed in media of not less than 1/6 refractive index. In addition to this we require special compensation oculars.

After going to this great expense what is the final result? We have an objective partly composed of flor spar and not stable in our climate. As a result we have what is known as "disease of the lenses "; the definition becomes obscure, and the objective has to be sent back to the maker, who after a short time returns it as good as new and without charge. These remarks apply to all objectives in which flor spar is used.

I do not think it worth while to send to Europe for our objectives when we can purchase them of American manufacture equal to those of Zeiss.

This is a strong statement, but I am justified in making it.

Spencer's Sons have always kept up the reputation of their father. There may be other firms who produce equally good work, but I am not equally familiar with their products.

I know that with a Spencer one tenth homogeneous immersion N. A. 1/38, belonging to my friend Mr. Henry Benett, I have resolved the dots in Amphipleura pellucida as clearly and distinctly as those shown by Dr. Henry van Heurck in The Microscope as the result of photographing the frustule with Zeiss's two-millimetre objective N. A. 1/63.

This result was achieved under the following conditions, which, by measurement, increased the N. A. of the objective from 1/38 to 1/32:

The objective was made with wide collar correction for use with a ten-inch tube, the English and American standard. By Dr. Henry G. Piifard's suggestion, the tube was shortened to the continental standard—six inches—the systems closed, monobromide of naphthaline used as immersion fluid for both objective and condenser, and a slide of Amphipleura pellucida, which I had mounted especially in media of nearly 2.5 refractive index, placed in position on the stage. The result was simply wonderful. The beads stood out as distinctly as those of Pleurosigma angulatum under a good immersion objective.

The same slide, under similar conditions, was afterward shown by Dr. Piifard to Spencer himself and Dr. Curtis, president of the American Microscopical Society. Both were delighted, and said they had never before seen such perfect resolution of the diatom.

I think Spencer's lenses, for all practical purposes, equal to Zeiss's; while, having no flor spar in their composition, they are not subject to disease. No special slides, cover glass, condenser, or eyepieces are required.

English authors have never given due credit to the genius of the elder Spencer. Carpenter, On the Microscope, in one of his earlier editions, refers to him in a footnote (1 quote from memory) in these terms: "A young man in Camastota, N. Y., has made some very fair lenses."

At this very time Spencer's objectives had been sent to England, tested with the production of their best makers, and easily proved superior. This injustice Carpenter has never corrected, and it has remained to Dr. Henry van Heurck, in his recent work on The Microscope, to render him full need of praise. He says, page 218, English edition, 1893:

"The firm of Spencer has been renowned for some time. The first information which we have about this house dates from 1848; at that time this optician's objectives were noted as surpassing those made in Europe. Shortly after, in 1852, Spencer manufactured a one-twelfth-inch objective having 1745°, the first having so large an angle of aperture.

"The firm of Spencer has always maintained its old reputation. Their objectives deserve all praise."

These grateful words come from probably the greatest living authority on the subject.

However, it is well to bear in mind that it is the brain behind the instrument, and not the instrument itself, that gives the result. Our opticians furnish us with instruments equal to all demands. It is to be hoped that some of our multiple millionaires will soon give some of their millions to found a permanent fund which will enable some of our most gifted students to devote their lives to original scientific investigations.
cent.—were due to tuberculosis; of a hundred and sixteen deaths among negro patients, forty-nine—forty-two per cent.—were due to tuberculosis.

A post-mortem examination was made in a hundred and sixty-three of these two hundred and ninety-five fatal cases—ninety-one white, seventy-two colored.

Indications of either healed, arrested, or still active and advancing tubercular disease were found in ninety-one instances—fifty white, forty-one colored.

No signs of tuberculosis, past or present, were discovered in seventy-two cases—forty-one white, thirty-one colored.

That is, fifty-five per cent. of the white patients and fifty-seven per cent. of the colored patients coming to the autopsies table exhibited the lesions of either a still active or a formerly existent tuberculosis.

Turning to the ninety-one tubercular cases, it is found that general miliary tuberculosis, i.e., tubercular nodules or larger masses in all or nearly all of the internal organs, existed in nineteen cases—four white, fifteen colored. Of these, three cases, all colored, could clinically be classed as "acute miliary tuberculosis."

The tubercular disease involved the lungs, lymph glands, and intestinal tract only (that is, if there were tubercular foci in liver, kidneys, spleen, etc., they were too small to be visible to the naked eye) in twenty-nine cases—sixteen white, thirteen colored.

The disease was confined to the lungs and bronchial lymph nodes in twenty-two cases—eleven white, eleven colored. In several of these cases death occurred from other causes.

The lesion consisted of a few small cheesy nodules in the lungs in five cases, all white.

Scars, chalky masses, fibrinous bands, etc., indicating complete arrest or cure of a former tuberculosis, were found in sixteen cases—fourteen white, two colored.

The facts above brought forward are of some interest from their bearing upon two points in the pathology of tuberculosis—the comparative susceptibility of the white and colored races to tuberculosis, and the frequency of recovery from the disease.

A. The Comparative Susceptibility of the White and Colored Races to Tuberculosis.—It is generally believed throughout the Southern States that the negro is more liable to tubercular disease than is the white man. The statistics of this hospital tend to show the correctness of this view; some twenty-five to thirty per cent. of the deaths among white patients are from tuberculosis; forty to forty-five per cent. of the deaths among the negro patients are due to the same cause. In addition to this, a study of our clinical records discovers the fact that in the colored race the disease assumes a much more active and rapidly progressive form, the average duration of fatal cases being markedly shorter in the negro. Very chronic forms of tuberculosis are rare among the negro patients, while the general miliary form is strikingly common. The reverse is true of tuberculosis in the white race. There are now in the hospital several white patients, known to have had the disease for years, in whom the malady is at a complete standstill, patients in tolerable bodily state and not emaciating; one of these has had the disease surely for ten years and probably longer; the physical symptoms were well marked eight years since, and the case at that time was regarded as one of chronic phthisis. The Bacillus tuberculosis was found in the sputum seven years ago. There are still evidences of consolidation and small cavities in both lungs, but the patient has not lost in weight—weights, in fact, a little more than she did five years ago, although during this time she sustained a fracture of the femur, making a fair recovery therefrom. There are also among the white patients now in the hospital possibly a half dozen or more in whom the disease has been to all intents and purposes cured.

Such cases as these, as above remarked, are of extremely rare occurrence among the negroes; there have been few cases in which the malady has existed for two years before death, and two only (in four years) in which entire arrest of the disease has been obtained.

The post-mortem findings, given in brief synopsis above, are especially interesting and significant as roughly outlining the comparative power of resistance of the two races to the spread of the infection. Reference to the figures will show that while the negro is but little more apt to contract the disease, a much smaller percentage of them recovered; to be specific, at fifty autopsies upon tubercular white patients the disease is found to be entirely healed or latent in nineteen, while in forty-one autopsies upon tuberculous colored patients healing or arrest is met with in two instances only. Several of these forty-one cases, however, had died primarily from some other cause than tuberculosis. Furthermore, in these fifty autopsies upon tubercular white patients, general miliary tuberculosis is found four times only, while among forty-one negroes fifteen show a general infection.

It is also worthy of note that during the four years embraced in this report the only two patients dying from excessive pulmonary hemorrhage in course of tuberculosis of the lungs were colored women; the only three cases of marked tubercular disease of the larynx occurred among the negro patients; the only case of tubercular meningitis was a colored man; the only instance of tubercular disease of the suprarenal bodies occurred in a colored woman.

It is then evident, in so far as conclusions from a comparatively small number of cases are warranted, that:

The mortality from tuberculosis is greater among the negro races than among the white.

The disease runs a more rapid course in the negro.

Cases of cure or arrest of the disease are comparatively infrequent in the negro.

The disease becomes much more widely diffused throughout the bodily tissues and organs in the negro, more than a third of the fatal cases showing a general infection.

B. Frequency of Recovery from Pulmonary Tuberculosis.—The time when tuberculosis of the lungs was regarded as a necessarily fatal disease has long since passed, and the trend of opinion, based upon careful clinical study as well as upon the results of post-mortem examinations, is toward a more favorable view of the possibilities of cure. Our re-
suits at the hospital, as will be seen by reference to the
condensed statement above given, would seem to justify
the belief that pulmonary phthisis is by no means so hope-
lessly fatal a malady as it was once held to be. From its
clinical side we see not a few cases offering undoubted
evidences of a commencing tubercular process in the lungs,
in which entire recovery is obtained; other cases in which
the disease, while not removed—in e., physical signs per-
 sist—undergoes arrest and is held in abeyance for years.

The patient previously referred to as having had the disease
for ten years is a good case in point. Another tubercular
patient, white female, has during the past twelve months had
an apparently complete arrest of a quite serious tubercular
process of long standing, and has gained in weight from
eighty two pounds eight months ago to a hundred and
three pounds at the present time. One of the two negro pa-
tients referred to incidentally above presents an equally good
example of arrest or remission. This patient was attacked
with tuberculosis in December, 1892; the Bacillus tubercu-
losis was present in the sputum, emaciation was progressive,
and the patient by midwinter was confined to bed. Shortly
after this time the disease came to a standstill, remained so
for a short time, then began to subside; all symptoms of
active tuberculosis vanished, and in the succeeding twelve
months the patient gained nearly fifty pounds in weight and
became able to engage in quite laborious manual labor.

The case has since been discharged from the hospital and
has passed out of notice. Before we had the opportunity
of verifying the matter by autopsies we were inclined, in
cases in which the Bacillus tuberculosis could not be de-
tected in the sputum, to doubt the correctness of the diag-
nosis in cases in which every vestige of evidence of tuber-
culos is disappeared; but a review of the autopsy records
brings to light a number of instances of healing of a tuber-
cular process. Note in the statement above made: In a
hundred and sixty-three autopsies, sixteen cases of prob-
able cure of a former tuberculosis are shown.

Briefly stated, these sixteen cases were as follows:

Case I.—White female, aged twenty-seven; died of ma-
nual exhaustion a few months after admission to the hospital.
No symptoms of tuberculosis during her term of residence.

Post-mortem examination discovered at apex of left lung,
lying just beneath the pleura, a cluster of hard caseous nod-
ules, the entire group not more than a quarter of an inch in
diameter, and surrounded by a firm fibrous capsule; some pleu-
ritic adhesions, old and firm.

Case II.—White man; died of septicemia and marasmus at
seventy-two years. Demented and in hospital many years. No
history of tubercular symptoms.

Autopsy discovered in center of upper lobe of left lung a
pea-sized chalky mass inclosed in a fibrous capsule. At apex
of same lung indurated areas and firm pleuritic adhesions.

Case III.—White woman, aged fifty years; epileptic; had
a kidney lesion, and died in uremic stupor. Five years before
her death she had a suspicious cough with occasional slight rises
of temperature, and for nearly or quite two years was in feeble
health and regarded as in an early stage of a pulmonary tuber-
culos is, although the Bacillus tuberculosis was not detected in the
sputum. She afterward improved and gained in weight, cough
disappearing; during the three years preceding her death no
tubercular manifestations were noted.

Autopsy.—At apex of each lung are found firm adhesions of
the pleura, indented scars, and in the underlying lung sub-
stance several patches and bands of firm fibrous tissue.

Case IV.—White man, aged thirty-eight years; died of
paretic dementia. No pulmonary symptoms recorded.

Autopsy.—At apex of each lung fibrous scars, pleuritic ad-
hesions, and in the underlying lung tissue, near the surface,
three or four millet-seed-like caseaceous masses.

Case V.—White man, died at seventy years, of arterial dis-
ease and general marasmus. No record of pulmonary symp-
toms.

Autopsy.—At apex of right lung firm pleuritic adhesions,
fibrous bands and patches, the latter containing in the center a
small mass of cheesy, chalky material.

Case VI.—White man, aged forty years; epileptic, and died
in stupor. No history of any lung complication.

Autopsy.—At apex of left lung a deep scar and indurated
patch, with firm pleuritic adhesions.

Case VII.—White woman, aged forty-two years; died of
Bright’s disease and exhaustion of excitement twelve months
after admission, having exhibited no symptoms of tuberculosis
during this time.

Autopsy showed firm pleuritic adhesions at apex of left
lung, with patches of induration and anthracosis; in the lung
immediately beneath this point there were several small semi-
solid cheesy nodules surrounded by a wall of white fibrous
tissue. In the lower lobe of this lung, near its posterior surface,
a small eighth-inch-in-diameter cavity haviing dense white fibrous
walls inclosing a little dry, granular material was discovered.

Case VIII.—White woman, aged sixty-four years, died of
arterio-sclerotic nephritis with a heart complication. No in-
dications of tuberculosis during the three months she remained
a patient.

Post-mortem examination discovered at apex of left lung
old, dense pleuritic adhesions; immediately beneath the pleura,
in the lung tissue, a single pea-sized, cheesy lump inclosed in a
thick ring of fibrous tissue, this latter surrounded by an anthra-
cotic zone.

Case IX.—Negro woman, thirty-seven years old, died of
nephritis. No tubercular symptoms recorded.

Autopsy.—Left lung at apex presents pleuritic adhesions,
fibrous scars, and in tissue beneath two small cheesy masses
with a wall of induration and anthracosis.

Case X.—Negro man, died at fifty-five years of age, of
uremia. No history of a probable tuberculosis.

Autopsy.—At apex of right lung old pleuritic adhesions,
a deep indurated scar, and radiating from this several fibrous
bands.

Case XI.—White woman, twenty-six years old, died of perit-
totis, having given no indications of tubercular disease of the
lungs during the seven months she was a patient of the hos-
pital.

Autopsy discovered at apex of left lung firm pleuritic ad-
hesions, indurations, and in lung tissue beneath the pleura se-
veral white bands and anthracosed areas; also five small granu-
lar and caseaceous millet-seed-like nodules inclosed in a wall of
fibrous tissue.

Case XII.—Man, white, aged forty-two years; died of cere-
bral hæmorrhage. No symptoms of tuberculosis recorded.

Post-mortem examination revealed at apex of right lung ad-
hesions of the pleura; a deep, indented fibrous scar; in under-
lying lung substance, fibrous patches with little gritty masses in
their centers.

Case XIII.—Woman, white, fifty years old; died of peri-
totis after a residence in hospital of fifteen years. During the
last ten years of this time she exhibited at intervals many of the
symptoms of pulmonary tuberculosis—cough, rises of temperature, one hemorrhage—and repeated examinations of chest were made; at one time it is noted that there is dullness on percussion over apices of both lungs, with expiratory roughness and many rales. After fluctuating somewhat during several years, the tubercular symptoms slowly disappeared, and the patient, as above mentioned, finally died of exhaustion following a pelvic peritonitis.

Autopsy.—At apex of each lung there are pleuritic adhesions, masses of fibrous tissue, chalky masses, gritty, sandlike patches interceded in fibrous tissue, zones of antracosis, etc. The entire mass was not so much as one inch in diameter in either lung. No active tubercular process anywhere discovered.

Case XIV.—White woman, in hospital twenty-three years, dying of venilinity and arterio-sclerotic nephritis at seventy-one years of age. It was noted in her clinical history in August, 1899, that she "presents every indication of phthisis palmonalis"; she then had cough, fever, and three hemorrhages. Subsequent history is negative. In the autumn of 1891 a careful physical examination failed to discover any signs of tuberculosis, and she died two years later without a return of the pulmonary symptoms.

Autopsy.—At apex of each lung pleuritic adhesions, scars on the pleural surface, and underneath several bands of fibrous tissue and small yellowish chalky masses.

Case XV.—White female, died of old age and malarious at sixty-eight years, after twenty years' residence in hospital. Six years before death she showed some tubercular symptoms, and during several years was regarded as suffering from pulmonary phthisis; she had dullness on percussion over both apices, with rales in same area; irregular rises of temperature, cough, scanty expectoration, etc. She unexpectedly began improving after this, fever and cough disappeared, and she gained twenty pounds in weight. She died three years later, having had no return of the tubercular symptoms.

Autopsy.—At apex of each lung pleuritic adhesions, deep scars, in lung tissue, numerous small fibrous bands at apex interspersed between chalky masses, some yellow, some white, friable, the entire mass being enveloped in a thin fibrous wall. In the lower lobe of right lung, near the center, a small cluster of cheesy nodules surrounded by a wall of antracotic tissue was discovered.

Case XVI.—Man, white, died at forty-seven years of age, of valvular heart disease. Had given some indefinite symptoms of tuberculosis.

Autopsy.—At right apex, adhesions and indentations; at left apex, adhesions, and in lung tissue, just beneath the pleura, chalky and cheesy masses enveloped in fibrous walls.

The pathological changes shown in the above-mentioned cases are those usually interpreted as the after-effects of healed tubercular lesions. There was recorded clinical evidence of tuberculosis in four of the cases only; in the remainder the attacks of tuberculosis may have occurred before the admission of the patients to this hospital, or the symptoms were so slight or non-characteristic as to attract no attention.

Our figures show, then, that of one hundred and sixty-three cases coming to autopsy, ninety-one, or fifty-six per cent., had at some time suffered from tuberculosis; of these ninety-one cases, sixteen recovered entirely; in five more the disease had been arrested and was making no progress whatever at the time of death from other causes than tuberculosis; and in nine other cases the disease was confined to small circumscribed areas in the lungs or other organs, pursued a very chronic course, and was not the direct cause of death. In other words, while more than half of the patients in the insane hospital at some time suffer from tuberculosis, one third of those who contract the disease make a good stand against it, either entirely recovering, or living for a term of years without being injuriously affected by small though unhealed foci of tuberculosis, or dying from some other cause in the course of a very mild and chronic form of the disease.

Necrosis of the Labyrinth.*

Report of a Case.

Opening of the Mastoid Process, Kuster's Operation.

Finally, Spontaneous Elimination of a Portion of the Labyrinth.

By Harry Friedenwald, A. B., M. D., Associate Professor of Ophthalmology and Oto-laryngology, College of Physicians and Surgeons, Baltimore.

Chronic supplicative inflammation of the middle ear may invade the surrounding structures and cavities and produce serious complications. At the annual meeting of this faculty a few years ago I had the honor of reporting a number of cases in which the principal secondary affections were inflammation of the mastoid process and septic intracranial complications (meningitis, thrombosis of the lateral sinuses).

To-day I wish to describe an interesting case in which the mastoid process and especially the osseous internal ear were secondarily involved.

Mary H., aged four years, came under my treatment in October, 1890, suffering from chronic supplicative otitis media of the left ear.

Previous History.—Sixteen months ago had scarlatinia, with severe scarlatinial diptheria and symptoms of meningitis. She was very ill for about two weeks, then recovered entirely excepting a purulent discharge from both ears. This was treated with injections and boracic acid, and the right ear rapidly recovered and has since then been entirely well. But the discharge from the left ear continued in spite of treatment. A few weeks before the case came under my observation a small piece of bone had escaped with the discharge.

Present State.—Auditory canal filled with offensive pus. A large polypus hangs from above, near the inner end of the canal, obscuring the deeper parts. The ear was thoroughly cleaned and a crescent-shaped piece of bone, on which the sulcus for the insertion of the drumhead could be distinctly recognized, was extracted. The polypus was removed with a snare. On the following day (November 1, 1890) the patient had a chill and high fever (103° F.). The fever continued for several days and the discharge was lessened, indicating retention of pus. The patient at times suffered great pain in the head.

November 6, 1890.—A consultation was held with Dr. Gumbel, the family physician, and the child was again accurately examined. The patient was weak and pale (the lungs, liver, spleen, and throat were normal). There had been no other chill, but the fever was still high (temperature 102° F., pulse 148). The child was very somnolent and the headache at times

* Read before the Medical and Chirurgical Faculty of Maryland at its semi-annual meeting, held at Cumberland, November, 1894.
was very great; but there were no other symptoms of cerebral complications (such as rigidity of neck, twitchings of peripheral muscles, sensitiveness of jugular vein, jaundice; the optic discs were normal). The discharge from the ear had again increased and it was occasionally bloody. The external ear was not sensitive, nor was the region of the mastoid process or the skull near the ear. The symptoms were therefore referred to retention of pus in the temporal bone, probably deep in the mastoid process, and cerebral complications were excluded. Having tried internal medication for almost a week without any improvement, we determined to open the mastoid.

On the following day, November 7, 1890, this operation was performed under chloroform in the usual manner. We were rewarded by finding a deep-seated abscess in the mastoid process, which was scraped and cleaned. The patient rapidly recovered from the operation, but our expectation that complete recovery from the aural inflammation would result was not realized. The wound closed rapidly, but the ototolea continued, though diminished in quantity, and the polypus returned. It was repeatedly removed with the snare, the curette, chronic acid, and with absolute alcohol. Whenever removed we could probe a curious cavity through a fistulous canal which had an opening about three quarters of a millimetre in diameter in the upper and deeper part of the osseous portion of the auditory canal. The purulent discharge remaining was the same, but was kept inoffensive most of the time by frequent irritation and boracic acid.

Fearing that the earlous process might extend, we determined to scrape out the cavity through the fistulous canal.

This operation was performed under chloroform May 3, 1891, but it proved ineffectual, and the polypus returned within two weeks. The former treatment was resumed. The patient's condition remained about the same for many months. Toward the beginning of the following year (1892) there were frequent attacks, during which the ear would become sensitive and painful; the patient would be restless and would sleep badly. There was frequently slight fever without chills. During these attacks the discharge diminished in quantity.

The recurrence of these attacks induced us to make another attempt to reach the source of the disease. In April, 1892, an operation was performed according to Kuster, consisting in the partial removal of the upper and posterior wall of the auditory canal with the chisel, after having laid the auricle forward by an incision along its posterior attachment. We soon entered the curious cavity, and this was scraped out as thoroughly as possible with a sharp spoon. No sequestrum was found. The cavity was packed and the patient again recovered rapidly, but again we were disappointed, for the ototolea recurred. We therefore gave up all hope of relieving the deep-seated caries by surgical means, and restricted the treatment to removing the polypus with the curette when it would become large, and to daily irrigations and instillations of a saturated solution of boric acid or insufflation of the powder. The discharge was not considerable in amount and was kept free from odor. We were finally rewarded for our patience, for in May of this year (1894) a sequestrum found its way into the auditory canal and was removed. The fistula closed and since then there has been no discharge whatever. The canal ends in a membrane occupying the position of the drumhead, but showing no landmarks, indicating that the ossicles have been lost and that the drumhead has probably been replaced by a eutricular membrane.

Many careful experiments have been made to determine whether there is any remnant of the function of hearing. These are very difficult and the results are doubtful in a child—now only eight years of age—but it appears certain that the hearing of this ear is entirely lost.

The sequestrum is small and is distinctly a part of a semicircular canal. It is crescentic in form, much thicker at one end than at the other, and its surface is very rough. On one side we find the canal mentioned above, of whose wall about a half is preserved. The sequestrum is seven millimetres long, two and a half wide, and about three thick.

Remarks.—Our patient at no time suffered from vertigo. This symptom, it is true, has not been frequently observed in such cases, as was shown by Bezold in his comprehensive study of this subject. When due to involvement of the semicircular canals, it is observed during the earliest period of invasion of the labyrinth. When this occurred in our case it is not difficult to surmise. It was probably soon after the onset of the attack of scarlet fever when symptoms which were referred to a meningitis appeared. These symptoms were in all probability due to acute supplicative inflammation of the labyrinth.

The origin of the labyrinthine affection deserves to be considered. Did it arise as a complication of suppurative inflammation of the middle ear, as was assumed at the beginning of this paper, or was it a primary affection? The former is much the more probable. There are a few cases on record in which the affection was probably primary in the labyrinth, but they are very few, and are not absolutely proved (cases of Christinnek, Trautmann, Toeplitz, and Kretschmann). The vast majority are secondary to the affection of the middle ear. Thus, in Bezold's list of forty-six cases there is but one which is probably primary.

We should also mention that there was never any facial paralysis, a very common symptom of necrosis of the labyrinth. One important feature of this case is the long course during which every possible attempt was made to relieve the sequestrum, but without success. To the patient cleansing, to keeping the fistulous canal free, and to the antiseptic treatment carried on without interruption for three years and a half, we may, in part at least, ascribe the final happy result.

922 Madison Avenue.

Reflex Spasm of the Tongue, Lips, and Pharynx induced by Irritation of the Great Occipital Nerve.—Gallarini and Pisaniotti (Neurol. Cirbl., 1893, No. 14: Circbl. d. med. Wiss., 1894, No. 19, p. 385) have reported the case of a man who had been struck upon the head twelve years previously. The site of injury was from time to time the seat of pain, both spontaneous and induced. In the stellate cecitrix a small, round, hard body could be felt, pressure upon which induced pain. There was present contracture of the muscles of the left side of the neck, so that the head was held downward and directed to the left, and there was also disturbance of speech, contraction of the lips, slight trismus, and some difficulty in swallowing. This spasmodic condition was a result of irritation induced by the presence of the foreign body, and disappeared after excision of the cicatrix at the point of union of the great and small occipital nerves.—Medical News.

PROMPT AID TO THE INJURED.

In the Progrès médical for January 26th there is an editorial article by M. Marcel Baudouin in which he deals especially with the question of first aid to the injured. The discoveries, he says, which have revolutionized modern surgery are, at the present time, according to operators, three in number, and they may be classified as follows: 1. Anæsthesia. 2. Temporary haemostasis. 3. Antisepsis and asepsis. Two of these discoveries, says the writer, are of unquestionable importance, and it may be said that without them the majority of large operations would never have taken place. But it must be added also that the latter, antisepsis, which by far holds the first place, would not have been able to have free scope if the Americans had not suspected close on to fifty years ago all that can be attributed to nitrogen protoxide and to ether as general anæsthetics.

Our estimate of temporary haemostasis as one of the wheels of progress during the past fifty years appears to the writer to be higher than is just. A well-known instrument-maker, says M. Baudouin, had recently gone so far as to call it pure exaggeration. However, this was modesty on his part, for he had played a certain part in the matter of forceps. But M. Baudouin adds that he does not agree with the instrument-maker. Without the means at our disposal at the present time for this temporary haemostasis, he says, many operations, particularly those that are directed against abdominal affections, would be impossible, and in any case would not bring success. The writer speaks of it intentionally as temporary haemostasis, for that only is important; the question of definitive haemostasis, which, for that matter, was determined long ago, indeed, before this century, does not present so many difficulties to surmount.

To these three discoveries, the real importance of which is admitted by the majority of surgeons, M. Baudouin ventures to add another. He does this with the less hesitation, he says, since he is neither its father nor its sponsor. He has reference to the hospital ambulance service of New York, which he characterizes as an extension of Baron Larrey's flying ambulance service to meet the wants of the ordinary citizen. He thinks that immediate surgical aid to the injured is one of the most important boons that have been introduced into surgery during recent years, ranking with antisepsis. It is one of the principal factors of success in operative surgery, other things being equal, and it should at once be put on a par with the three discoveries that he mentioned at the outset. From a purely surgical point of view it is even more valuable than the suppression of pain, anæsthesia. This is easy to understand, he says, but it will be more difficult to make the wounded person comprehend that he should endure even the smallest intervention.

This theoretical idea is due entirely, in so far as concerns its scientific and rational application, to the practical sense which is so remarkable in Americans. It is time, says M. Baudouin, to organize in all the great industrial centers of Europe a service of prompt surgical aid to the injured, and to establish ambulances of great speed, for they are indispensable to such a service, if surgery is expected to make notable progress in the future. The writer urges this point because he believes that an entirely new organization must be instituted independent of that of former years. If we are stingy in these matters, he says, the end will not be attained. It is much better not to attempt anything than to compromise the principle by insufficient experiments, and especially to undertake an expenditure which will not bring any appreciable result. M. Baudouin speaks of M. Eloy as having, in the Journal des praticiens for January 10th, drawn the attention of the medical profession to such efforts, and for this, he says, he is very grateful to him. The negligence and the obstinate ignorance of the public ministers, says M. Eloy, are astounding. We who know, says M. Baudouin, how much the Municipal Council of Paris has it at heart to overcome this difficulty, are persuaded that the solution so long expected will not be delayed, and that we may soon commend the active and prudent councillor who shall arise as the promoter of this great and generous work.

THE MEDICAL SERVICE OF THE NEW YORK STATE MILITIA.

Surgeon-General Bryant's final report, dated December 1, 1894, a pamphlet of forty-eight pages, brings out very clearly, but with the utmost modesty, the great service that he and the medical officers serving under him have rendered to the State. It reviews the affairs of the medical corps during the ten years ending with the close of last year. Nobody who is in a position to compare the corps's present dignity and efficiency, the respect paid to it by the line officers, with its condition at the beginning of Dr. Bryant's term of office can fail to see how notably it has advanced. Among the salient causes of this advance, as we learn from the report, are the emancipation of regimental medical officers from dependence on commanding officers' personal preferences in the matters of their appointment, retention, and treatment; the experience gained by actual service annually in camp; the successful establishment and proved value of the hospital corps, which was for some time strenuously opposed by many of the very line officers who are now proud of it; the provisions for the physical examination of recruits; and the furnishing of the various regiments with an approach to adequate appliances for the care of the sick and wounded, whether in the commands or among civilians in times of unusual turmoil or calamity. Dr. Bryant recommends the purchase of four ambulances, one for each brigade.
The report has the touching quality of a farewell address, especially in the peroration, as follows: "The medical officers of the entire service have been uniformly considerate and courteous on all occasions. Each has labored in his own way most faithfully to maintain the dignity and increase the standard of the professional excellence of the service. To whatever the future may give birth, surely nothing can happen that will dim the recollection of the pleasant associations and the labors of love that have characterized our past official intercourse. The official and personal relations with the general staff have been pleasant and instructive in the fullest degree. The kind consideration and the thoughtful attention that have been accorded to me under all circumstances by the Commander in Chief and my official colleagues form an epoch in life the recollection of which is of the pleasantest nature. The thought that 'Recollection is the only paradise from which we can not be turned out' (Richter) affords much comfort to those who are fond of sweet memories."

ITEMS, ETC.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending February 19, 1895:

To Military and Naval Medical Officers.—The undersigned, members of the committee on litter appointed by the Association of Military Surgeons of the United States to report at the approaching annual session a desirable form of military litter for the comfortable, safe, and expeditious transportation of the sick and wounded, solicit from medical officers of the national services and the National Guard of the several States suggestions, plans, or models of such an appliance, to be delivered to either of them at their respective addresses, on or before the 1st of April, 1895:

ALBERT L. GHION, Medical Director of the U. S. Nuey, U. S. Naval Hospital, Washington, D. C.

MYLES STANDISH, Captain and Assistant Surgeon, M. V. M., No. 200 Dartmouth Street, Boston, Mass.

Marine-Hospital Service.—Official List of the Changes of Stations and Duties of Medical Officers of the United States Marine-Hospital Service for the Fifty Days ending February 15, 1895:

PURVANCE, George, Surgeon. Detailed as chairman of the board for examination of assistant surgeons for promotion, to convene in Washington, D. C., March 11, 1895. February 8, 1895.

HILTON, J. B., Surgeon. Granted leave of absence for six days, February 7, 1895.

AUSTIN, H. W., Surgeon. Detailed as member of the board for examination of assistant surgeons for promotion. February 8, 1895.

IRWIN, Fairfax, Surgeon. Detailed as recorder of the board for examination of assistant surgeons for promotion. February 8, 1895.

EAGER, J. M., Assistant Surgeon. Ordered to examination for promotion. February 9, 1895.

BLUE, REPEET, Assistant Surgeon. Granted leave of absence for six days. February 13, 1895.

NOEMAN, SEATON, Assistant Surgeon. Ordered to examination for promotion. February 9, 1895.

Society Meetings for the Coming Week:

Monday, February 25th: Medical Society of the County of New York; Boston Society for Medical Improvement; Lawrence, Mass., Medical Club (private); Cambridge, Mass., Society for Medical Improvement; Baltimore Medical Association.

Tuesday, February 26th: New York Dermatological Society; Buffalo Obstetrical Society.

Wednesday, February 27th: New York Academy of Medicine (Section in Laryngology and Rhinology); New York Pathological Society; New York Surgical Society; American Microscopical Society of the City of New York; Metropolitan Medical Society, New York (private); Auburn, N. Y., City Medical Association; Medical Society of the County of Albany; Philadelphia County Medical Society; Berkshire, Mass., District Medical Society.

Thursday, February 28th: New York Academy of Medicine (Section in Obstetrics and Gynecology); New York Orthopedic Society; Brooklyn Pathological Society; Roxbury, Mass., Society for Medical Improvement (private); Pathological Society of Philadelphia.

Friday, March 1st: Practitioners' Society of New York (private); Baltimore Clinical Society.

Saturday, March 2d: Clinical Society of the Post-graduate Medical School and Hospital; Manhattan Medical and Surgical Society, New York (private); Miller's River, Mass., Medical Society.

Answers to Correspondents:

No. 432.—The article has the appearance of an advertisement in disguise. We know nothing about the man.

Births, Marriages, and Deaths.

Married.

HENRIQUES—OAKLEY. In Morristown, N. J., on Thursday, February 14th, Dr. H. A. Henriques and Mrs. Alice Dudley Oakley (nee Mulligan).

Died.

ASHTON. In Philadelphia, on Monday, February 11th, Dr. Samuel K. Ashton, aged seventy-three years.

BAILEY. In Pittsfield, Mass., on Saturday, February 9th, Dr. Charles Bailey, aged seventy-four years.
Bowles.—In Springfield, Mass., on Tuesday, February 12th, Dr. Stephen Wallace Bowles, in his sixty-sixth year.

Rose.—In Palmyra, O., on Tuesday, February 12th, Dr. L. C. Rose, aged forty-five years.

Letters to the Editor.

THE "DEVELOPMENT" OF INSANITARY CONDITIONS.

WASHINGTON, February 18, 1895.

To the Editor of the New York Medical Journal:

Sir: I set too high a value on the columns of the Journal to occupy space in discussing the meaning of a word which may be found in "Webster" or any of the other dictionaries; but as an editorial in your issue of February 9th calls in question the applicability of the word "develop" in the third paragraph of the bill to appoint a commission to investigate the subject of the pollution of rivers and other natural sources of water supply, and reflects on the literary qualifications of those concerned in framing the bill, I feel called upon to claim space for a few words, as I had the honor to draft that bill at the request of those interested in the subject.

"One of the sections," your editorial states, "provides that 'at the next session of Congress the commission shall submit such suggestions as may seem desirable for the purpose of remedying any insaneitary conditions that may have been "developed" by its work.' Surely this is not what the framers of the bill meant, for he can hardly intend that the commission shall go into the business of developing insaneitary conditions; he has simply lapsed into sloppy English." This is precisely what the framers of the bill meant and intended. The transitive verb develop means to take a thing out of the wrappings or obscurities in which it is enveloped. The thing referred to is in existence, but it is not apparent until its existence is developed by some agency. It may be intangible, an idea, for instance, but the existence of the idea may be developed by the use of words spoken or written. It may be invisible as is the photographic picture, which can be seen only after it has been developed by certain chemical solutions, or it may be a very material and substantial thing, as a hostile army in line of battle, the position of which may be developed by reconnoitering parties. The first two illustrations are analogous and the last is the homologue, from the literary standpoint of the insaneitary conditions which may be developed [Synonyms: uncovered; unfolded; laid open; disclosed; exhibited; unraveled; disentangled; detected.—Webster] by the labors of a commission of competent investigators.

Some persons, through ignorance or carelessness, use the word in the sense of to produce or to cause to come into existence. Against these the charge of lapsing into slovenly English may be preferred with justice, but certainly not against those who give the word its true value.

Please oblige me by publishing this communication, that the unmerited slur on the language of H. R. 8481 may not be passed over in silence.

CHARLES SMART,
Major and Surgeon, U. S. A.

METHODS OF TREPHINING.

ANNISTE, N. Y., January 25, 1895.

To the Editor of the New York Medical Journal:

Sir: In your Journal of January 19, 1895, under the heading of A Method of Trephining, reference is made to an article by J. M. Cotterill, M. D., F. R. C. S. Ed., published in the January number of the Edinburgh Medical Journal. In this article Cotterill proposes a new and, as he maintains, an expeditious method of opening the cranial cavity without much loss of bony tissue, as in ordinary trephining. Undoubtedly the preservation of the wall of the cranum in its integrity is of the greatest consequence, in that it makes it possible to secure repair of the excised disc of bone and subsequent protection to the intracranial parts. Such an article as this one referred to should create considerable sensation in the surgical world, not, however, from the originality of the idea, but rather from the fact that at this late date a claimant should appear for honors long since won by another. In the New York Medical Record of February 10, 1894, appeared an article by Dr. J. S. Pyle, of Canton, Ohio, describing a new method of opening the cranial cavity by means of what is known as the diamond drills.

On comparing Pyle's and Cotterill's operations, one can readily observe the simplicity of the former as compared with the latter. Pyle's is a short, direct method of accomplishing a definite purpose, while Cotterill's is laborious and complicated. Pyle incises the scalp in the selected place and, with a sliding or rocking motion, cuts quickly through the skull with his diamond drill, leaving a small peninsula of bone uncut. This peninsula is fractured in laying back the flap, but the circulation in the loosened fragment of bone is not interfered with. The parts coagulate nicely, bony union is established, and the cranial contents are better protected than by the old trephine method.

Cotterill's method, with its complicated incisions and numerous perforations, arrives at the same result, but by a more devils route. In no respect does it surpass Pyle's operation. It has no claim on the profession not fully covered by its predecessor. The diamond drills have come to stay.

FRANKLIN SHOFF, M. D.

Proceedings of Societies.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Meeting of November 23, 1894.

The President, Dr. De Forest Willard, in the Chair.

A Demonstration of a Mechanism of Intussusception.—Dr. Robert T. Morris, of New York, by invitation of the board of directors, made the demonstration. He exposed the ileum of a rabbit, and it was observed that when it was touched with sodium carbonate contraction of the circular fibers of the bowel at the point touched would take place in from fifteen to thirty seconds. The longitudinal fibers of the bowel still carrying on peristaltic movement (a reversed peristalsis, by the way), would invaginate that portion of the bowel which was in a state of firm contraction. He did not know the exact value of this experiment, except that it showed the mechanism of one form of intussusception. We knew that certain ptomeines produced muscular spasm, and it was fair to assume that some cases of intussusception were due to a poisoning of the muscular fibers of the bowel, as in the experiment. In post-mortem intussusception, as he had watched it, there had been paralysis of the circular fibers of the bowel, and an adjacent segment of bowel had dropped into the relaxed portion, almost the reverse of the mechanism demonstrated in this experiment.

Specimens Illustrating Each Step in the Progress of Infective Appendicitis were then shown by Dr. Morris, who said he believed appendicitis to be an infective exudative inflammation of the appendix vermiformis, which followed the production of an infection atrium of any sort in the mesosa or in the peritoneal covering of the appendix. He believed that
when the infection ation had been produced, bacteria at once entered the lymphoid structure and the cellular coats, and that then the stage of exudation began and the tissues were compressed by the exudate. There was no doubt that in the majority of cases there was an exudative compression which was fatal or had a tendency to be fatal to the lymphoid and cellular coats, and the reason was because the lymphoid and connective tissue and mucosa were confined within a narrow tube of muscle and peritoneum. The lymphoid tissue could not do its work as a strainer of bacteria, and therefore the lymphoid, mucosa, and connective tissue forming the inner tube were compressed to the point of strangulation in many cases. If not to the point of strangulation, compression anemia was produced, which allowed of more rapid toxic destruction of the cells, and the toxins produced by the bacteria which had entered the infection atrium caused destruction of the cells before leukine could be poured out and the leukocytes did their work. Thus there was a frequent rapid destruction of the mucosa and lymphoid coats which should act as a protecting coat, but which were destroyed and became a prey to bacteria because they were under compression.

Proliferative endarteritis began very early, and this occurred in a small terminal artery, for, practically, the only arterial supply of the appendix was from a solitary terminal artery. If a branch of the artery became occluded, a round punch-hole slough formed at the point supplied by this branch. If more of the artery became obliterated there was frequently complete gangrene of the appendix. Only a few hours were required for an obliterating endarteritis to become sufficiently marked to lead to destruction of all parts not supplied with blood by bacteria which were ready to pounce upon such parts. He thought that usually in the very early stage of the infection there was a mixed infection. Streptococci were apt to be present, and these with other bacteria sent the temperature up. The temperature from infection by streptococci or from mixed infection might be quite high, whereas when the infection was from the colon bacillus the temperature was not apt to be high, but about 101° to perhaps 102° during a most violent attack of infective appendicitis going on to death. This statement in regard to temperature the speaker was almost prepared to make as a direct statement, but he would wait for more observations before asserting that a high temperature indicated streptococci or mixed infection, and that a low temperature indicated a colon-bacillus infection. He was almost certain, however, that the toxine of the colon bacillus did not send the temperature high.

Dr. Morris showed a normal appendix which had been removed post mortem.

Another specimen showed the effect of exudation into the appendix a few hours after infection had taken place. The inner tube, composed of the lymphoid and connective tissue, was distinctly swollen. In a third specimen a little rhexis was found, all the structures being infiltrated with blood.

There was a complete rhexis involving all the tissues in the fourth specimen, the fibers of all structures being separated by effused blood. In the patient from which the specimen had been removed the wound had been very septic and no granulations had formed for eight days. The patient had then had pneumonia of the right side, and after the pneumonia had been well under way the appendix wound had begun to granulate and the patient had recovered.

The fifth was another early specimen, in which there was a pin-hole puncture. In this case the appendicitis had lasted about forty-eight hours. The artery being obliterated at this point, had allowed a small pin-hole opening to form.

The sixth specimen, an inch of which had been removed, showed very clearly how the interstitial exudation caused the inner tube to be compressed by the outer tube.

A specimen was shown in which the bacteria had been confined to the appendix for several days and then had suddenly passed through the mesappendix, and the patient had had acute septic peritonitis.

Dr. Morris exhibited another specimen in which a small pinhole perforation had formed and had been immediately walled in by lymph. The appendix had been quite free except at the tip, where this mass of exudate had held it. This was a chronic ulcerating appendix. After the acute stage of infection was passed the ulceration was apt to continue, because the appendix was a nodd in which bacteria persisted, and after the mucous membrane was destroyed the bacteria were apt to keep up a vigorous onslaught on the exposed tissues. These were the appendices that produced fatty concretions. He had found that concretions in the appendix were phosphatic, fœcal, or fatty. Some of these concretions contained fifty per cent. of fat. It had occurred to the speaker that possibly a retrograde change in the lymphoid might account for it, and consequently he had submitted the lymph coats of several appendices for examination. From normal appendices he had obtained eight per cent. of fat; from appendices with small ulcerated spots, nineteen per cent.; and from appendices with general ulceration of the mucous and lymphoid coats, twenty-six per cent. This had shown that the proportion of fat in chronic ulcerating appendices was very large, and if the products were confined in the tubes it was probable that these fatty concretions came from that source.

Before gangrene in the appendix had occurred we sometimes found gangrene of the mesappendix from thrombosis of the veins and obliterating endarteritis. Sometimes the appendix seemed to receive enough nutrition from the cæcum to live a few hours longer than the mesappendix.

After infection had continued for some time—a few years—frequently found excessive hypertrophy of the appendix. This specimen showed this hypertrophy in an appendix which was the seat of chronic ulceration. Most of the time the patient had been without symptoms, but at times he had been compelled to give up work. He had found the appendix extremely tender on palpation, and had learned that of late the patient had referred the pain to that region.

In some cases after destruction of the mucous gradual wasting of the lymph coat took place. This was shown in a mount of four transverse sections. In the first, the mucosa and submucosa were swollen with exudate. In the next the mucous coat had disappeared and the lymphoid had almost disappeared. In the next nothing but the muscular and peritoneal coat remained, and in the last there was no lumen and only a little remnant of the muscular and peritoneal coats.

In cases in which the terminal artery was involved quickly in proliferating endarteritis the entire appendix might become gangrenous. The speaker showed an appendix which had become completely gangrenous in thirty-six hours. No portion of this appendix had remained alive, and there had been an opening of about two inches in the cæcum.

After the various structures had disappeared, leaving little but the muscle and the peritoneum, there might be marked symptoms from sclerosis of the nerves. The nerves of the appendix not destroyed became involved in the electrical contraction and frequently kept up a great deal of disturbance in this vicinity, and not infrequently the movements of the colon were inhibited. As a result there was apt to be chronic consti-
He had removed several such stumps and the patients had immediately felt relief.

The patient from whom this specimen had been removed had had several attacks of appendicitis, and on removing the appendix Dr. Morris had found that it was filled with nematoid worms. The cecum was a favorite resort for the oxyuris, and he had no doubt that the presence of the oxyuris in the appendix not infrequently gave rise to an infection atriun.

Another specimen showing three distinct cavities with contractures between was presented. It had been extremely firmly adherent. The patient had had a number of mild attacks, and once an abscess had opened externally, and finally it had been found necessary to remove the stump, which contained three well-marked cavities similar to what we often saw in pus tubes.

Among the latter forms was one represented by two specimens which had been removed from a professor in one of our colleges. He had been unable to stand and had been compelled to give up his work for a year. On removing the appendix Dr. Morris had found these two portions some distance apart. The little short stump represented the healed appendix. The lower portion had been an inch and a half away from the stump. It had been a focus of infection, and had been kept alive by adhesion to surrounding tissues.

If we were to consider the complications of appendicitis, he said, we should open up an enormous field. He simply showed a specimen belonging to Dr. Willard. Here, he said, we had an abscess of the liver, which was not an infrequent complication, and probably occurred oftener than was generally supposed. In very mild cases, and in cases in which the infection had been in progress for not more than two days, he had found infected thrombi in the mesappendix, which might easily lead to emboli and abscesses of the liver. He was quite sure that this occurred in cases where appendicitis was not suspected. It was not necessary that there should be gangrene or extensive disease of the appendix to have mesenteric thrombosis and portal embolism.

Dr. John Ashhurst, Jr., said that he had listened with a great deal of pleasure to the description of Dr. Morris's specimens, and that there were some points that had particularly interested him. What Dr. Morris had said with regard to the occurrence of inflammation of the appendix followed by gangrene from pressure, the appendix being a narrow tube, and therefore not able to bear great distention with impunity, was paralleled by what was seen in other parts of the body. We saw it in some cases of felon, where the tension became very great from the temporary hypertrophy, as it had been called by Virchow. When such a finger was opened, no pus and but little blood might escape, but the whole finger might be apparently packed with dead or dying tissue. This was also an instance of necrosis from tension, due to excessive inflammation where there was no chance for expansion. He had seen the same thing in the testis, where necrosis of a considerable portion of the gland might take place from the firm tunica albuginea preventing expansion of the inflamed organ.

He had also been interested in the specimens showing obliteration of the lumen of the appendix. He had seen such specimens. Several weeks ago he had removed the appendix of a young lady who for many years had suffered from recurrent attacks of appendicitis, and between the attacks had had curious symptoms, referred to the digestive system, which he thought were explained by the condition which had been found at the operation. In this case the appendix had been so much reduced in size that it had been discovered with great difficulty. It had been simply a fibrous band surrounded by serous membrane. No mucous membrane could be seen except a little pouch near its junction with the cecum.

The speaker had been interested in what had been said with regard to the causation of reflex symptoms, such as interference with the function of the bowel, which had been explained by a condition of local neuritis. In the case to which he had just referred, the patient had suffered for years with almost continual nausea, although without vomiting. She could not take a meal without suffering with nausea for hours afterward. He thought that the digestive symptoms had been explained by the presence of adhesions. The cecum had been closely adherent to the abdominal wall, and it was easy to understand that under such circumstances the nerves of the part would be seriously pressed upon, and neuritis might follow. We found an analogy to this in cases of Littre's and Richter's hernia, where a diverticulum of the bowel, or a small portion of the intestine, was caught in a hernial opening. In such cases there might be grave symptoms of strangulated hernia, though only a small portion of the lumen of the bowel was involved.

Dr. Morris had referred to the presence of worms in the appendix. Last winter the speaker had operated in a case of acute appendicitis in which, after evacuating a quantity of pus, he had seen what he supposed to be an unusually long appendix, but on bringing it out he had proved to be a lumbricid worm loose in the peritoneal cavity, the explanation of its presence being, of course, that it had escaped through a perforation.

Recently he had operated on a patient who had been operated on in Brooklyn four years before for appendicitis, and who had supposed that his appendix had been removed. Two years after the first operation the cecitum had reexpanded and had discharged a small quantity of pus, and since then a fistula had remained. When he had come under Dr. Ashhurst's care he had been advised to have the cecитum divided and the part explored, as it was possible that a silk ligature might be keeping up the discharge. On making an incision, the finger at once had entered the abdominal cavity, and the speaker had felt a full-sized appendix. The case evidently had been one where the surgeon had opened an abscess, and very judiciously, in all probability, had not pushed the investigation further. He believed that in many cases of acute appendicitis the safety of the patient depended upon not making too minute an exploration. If the appendix was not readily found it might be permitted to remain. In this case he had removed the appendix in the ordinary way, and had found it partially obliterated. There had been two diaphragms, as it were, making pouches, and in one of these there had been a pin-hole perforation. The lesson taught by this case was, that when it was possible to remove the appendix without too much disturbance, it should be done; but, as he had just said, he believed that there were cases where the line of safety for the patient rested in not making too minute an investigation, and, if the appendix could not be readily found, in leaving it, and simply evacuating the pus.

Dr. James C. Wilson said that Dr. Morris had rather thrown out some suggestive hints with reference to the pathology of appendicitis than gone thoroughly into the discussion of any particular branch of this wide and complex field of surgical pathology. He would have been glad if Dr. Morris had been able to have given his views more fully in regard to this affection.

He was particularly impressed with what had been said in regard to the remote changes and with the explanation which had been suggested for some of the chronic and troublesome intestinal disturbances which had been so unaccountable in their pathology. He thought that we had all been puzzled and had been unable to explain or to give relief in many cases which probably came within this group of chronic appendicitis, with nerve changes, adhesions, and permanent foci of infection,
PROCEEDINGS OF SOCIETIES.

Feb. 23, 1895.]

giving rise to persistent disturbance not yielding to treatment. He had had many such cases, which had been classified under the head of chronic intestinal indigestion with nervous symptoms. The difficulty which he found in cases of this kind was to induce the patients to subject themselves to a surgical operation. In one such case of long-standing ill-health, in which Dr. Deaver had been associated with him, a discussed appendix had been found, and after some months the patient reported that she was greatly improved and had regained her health.

Dr. John H. Mussen said he had been particularly interested in the suggestion thrown out by Dr. Morris with reference to the degree of virulence of the symptoms depending upon the character of the infection; that where high fever was an initial symptom the probability was that there was infection with the streptococcus, a form of infection which he knew very well was not likely to yield to treatment. We also knew that the possibilities of more remote infection were greater, and the liability to infection of the peritoneum infinitely greater. If in this way we could determine the character of the infection we should be more guarded in our prognosis and in our treatment. He thought that cases of severe streptococcus infection should be treated early by operation.

He had also been interested in noting that in the pathology of appendicitis we saw that there were two causes for the symptoms, the one mechanical and the other the septic process, the septic process being responsible for the temperature, the mechanical process being responsible for the pain, for the reflex vomiting, and likewise for the occurrence of further pathological changes, such as gangrene. The specimens readily demonstrated that it was impossible to tell whether or not gangrene was going to take place. We could not tell from the local symptoms or from the fever whether or not there was going to be perforation. As we well knew, some of the simplest cases, so far as symptoms were concerned, often resulted in gangrene, and patients might be discharged apparently convalescent when gangrene was going on. He had seen patients operated on at the end of a week or ten days, and gangrene had been found, the presence of which the earlier symptoms had given no indication.

In analogy with streptococcus infection under other circumstances, he said, we noticed here the tendency to recurrence and the tendency to infection of other tissues. He asked Dr. Morris if the cases of recurring appendicitis were not largely of streptococcus origin. He had had a case of this nature. If this was true, it was another argument in favor of resort to operation in these recurring cases.

He had had several opportunities to observe cases of chronic intestinal disturbance due to continuous infection from the appendix, and the removal of this small focus of infection had proved of the greatest value, having resulted, indeed, in the cure of the patient.

Dr. Ernest Laplace said he had been especially interested in the remarks with reference to the relation between the nature of the infection and the temperature. It would be very well indeed if such a relation could be established, but he thought it was entirely vain. Even if we were prepared to say that in appendicitis there were only two forms of infection, that by the streptococcus and that by the common colon bacillus, he should be prepared to say that there would be no two patients in whom the reaction to these points would be exactly the same, and that there were some systems on which the phenomena of the streptococcus had very little irritating effect and produced very little elevation of temperature, and therefore the temperature at no time was a real index of the severity of the case.

Another point was the relation of intestinal symptoms—intestinal atony to the possible degree of nerve fixation by fibrous tissue resulting from chronic inflammation. He was sorry that Dr. Morris had not given the results obtained in the cases referred to. The speaker's experience in the removal of scar tissue, not only from this part but from other regions, and especially where serous membranes were involved, was that the reproduction of scar tissue was as rapid as before, and he doubted the wisdom of disturbing strong fibrous adhesions, which merely resulted in a little nerve disturbance in the intestine, in order to relieve that condition. We all knew that once Nature had done the work for us we should respect that work, because she had done it better than we could. If we removed this fibrous tissue we left a surface which must granulate and form new fibrous tissue, and the result was the same as before, the same nerves were apt to be affected, and the patient was as badly off, plus the danger of the operation.

The specimens showed, he said, that Dr. Morris had gone deeply into the philosophy of the subject, and the points brought out in the surgical pathology of this affection were interesting and solved many points which had been problems with him.

Dr. John B. Roberts remarked that he should like Dr. Morris to give what evidence he had that neuritis existed in the cases mentioned. The doctor had not gone into the subject of the operative surgery, but had confined himself to the portion which was the more important at this time—namely, the pathology. The speaker would be glad to have him tell whether in his operative work he went upon the principle of a possible neuritis and secondary digestive trouble due to the retention and binding down of the appendix. Did he always make a search for the appendix in the primary operation, even where there was a great deal of pus, or did he evacuate the pus and wait for a subsequent period to remove the appendix? In operations where a short stump had been left he had seen evidences of digestive trouble from fibrous contraction, or were neurotic symptoms found only in cases cured by Nature?

Dr. John B. Deaver said there were only one or two points to which he should refer. The first was the separation of the appendix, to which Dr. Morris had referred, where we found the stump and then the tip of the organ at some little distance. He had met with a similar condition where the tip of the appendix had been the source of the infection. In one of these cases the tip had been behind the colon and had contained an abscess.

The pain in chronic appendicitis he had no doubt was due to neuritis in certain cases. He also believed that it was due to traction made on the adhesions. He thought that this was particularly true after operations where we were called upon to remove stumps, and it should make us more careful in treating stumps. Where it could be done the stump should be invaginated and the serous coat of the cecum stitched over it. The nerves reached the appendix through the mesappendix, and where the mesappendix was not greatly infiltrated we should eliminate the elements of neuritis and look for some other explanation. He believed, therefore, that in these operations followed by severe pain, which was referred to the right iliac region and aggravated by certain motions of the body, it was warrantable to reopen and examine the stump of the appendix, if we could find no other explanation for the pain.

Gangrene of the mesappendix he had seen in a certain number of cases. In one such case the mesappendix had been gangrenous, while the appendix had been practically intact, the operation having been done very early. Dr. Deaver mentioned a case of abscess of the appendix. The patient had but few symptoms either general or local. It had been suggested to him that he had appendicitis, and he hid at once agreed to
an operation. The appendix had been perforated at its mid-
point in the line between the two layers of the mesoappendix,
among the abscess, which had contained half a drachm of pus,
extraperitoneal.

With regard to streptococcus and colon-bacillus infection,
he believed that the streptococcus was the most virulent, and he
believed also that this played a rôle in certain of the cases with
high temperature. It was not the cases with high temperature
that he feared. It was the cases with moderate fever that were
apt to deceive us. He placed little reliance on the temperature,
but was governed by the local condition, the presence of peri-
tonitis, and by progressive invasion of the peritoneal cavity.

The results of operations, so far as his experience went, had
been very satisfactory. He had not found reflex disturbance
follow removal of the appendix where he had been able to dis-
pose of the stump in the ideal way. Where this had not been
possible, on account of dense adhesions, or on account of the
fear of breaking down the limiting wall which Nature had thrown
out, he had seen pain follow, which, in some cases, had sub-
sequently been demonstrated to be due to adhesions.

Dr. G. G. Davis asked Dr. Morris what his view was as to
the relation which infection bore to appendicitis. In other
words, if there was one form termed infectious, what other
inflammations of the appendix were there? Infection had been
said to be a cause of intestinal catarrh. Might the process also
be a reversed one? Did the doctor recognize such a thing as a
catarrhal process being a cause of appendicitis?

Dr. M. Pance thought that Dr. Morris should have taken up
more than the pathology, as those who were doing operative
work cared very little about the pathology of appendicitis; they
cared more about the condition found at the time of operation.
He recognized two entirely different conditions with which we
had to deal—one where the bowels were confined and it was
impossible to move them, and the other where the bowels could
readily be moved. These conditions were to be dealt with dif-
ferently, although both were from the same original cause.

As regarded temperature, he said, in twenty-three abdomi-
nal sections for appendicitis, with nineteen consecutive recov-
eries, he had never seen but one case where the temperature
had not been below normal. In looking over the report of Dr.
Keen's cases, in a paper in 1891, he noted that in two thirds of
them the temperature had been below normal. He noticed the
same thing in the reports of other operators; the temperature
was below normal at the time that the case came into the hands
of the operator. Of course, in the cases that had come into the
speaker's hands, the disease had existed from twenty-four hours
to three or four days, and there had been time for pus to form.

There was no question that there were nervous symptoms
caused by pressure upon nerves. This was sometimes seen after
amputations where resection of the nerve might subsequently
be required. He had seen it beautifully illustrated in a case
recently in Dr. Joseph Price's hospital. The patient had been
unable to walk when admitted. Both appendages had been
removed, it was supposed, close to the uterine. It had been a
dirty case, requiring drainage. After recovery she had still
complained of pain in the right iliac fossa. On reopening and
excising the right stump it had been found that the ligature
had not been encapsulated, and four or five drops of pus had been
in the stump. This had been removed and the part cured, and
in six weeks the patient could walk as well as any one.

The speaker knew that Dr. Morris believed in clean surgery
and in complete surgery, and he would ask if the doctor would
be willing to leave in the pelvis such a mass as Dr. Laplace
had referred to, and hope for perfect results. He did not see where
Dr. Laplace got his data when he said that the same fibrous con-
dition existed after we had removed the offending cause.

He asked Dr. Morris concerning the mortality, in view of the
fact that in the Johns Hopkins Hospital they had had eight
death in nine operations. Christian Fenger had reported
eleven consecutive deaths in appendicitis operations. He be-
lieved that all these patients ought to get well unless they were
practically dead at the time of operation. The radical men who
believed in surgery were to-day saving nine out of ten of the pa-
tients. He believed that the reason of the deaths was that
complete operations were not done. He agreed with Dr. Ash-
urst, that if the bowels were soluble and there was an abscess,
the only thing to do was to open and drain, because the patient
would get well. He believed that all deaths after operation
were due to bad judgment or to bad surgery—the man either
operated on a dying patient or he did bad surgery.

Dr. Joseph Hoffman thought that it took only a few such
specimens as had been shown to convince one that appendix-
tis was naturally a surgical disease. Clinicians had generally con-
sidered this affection in the light in which they had formerly
regarded tubal and ovarian troubles, but when specimens had be-
gun to be circulated, and the condition of the tubes had been
seen, the propriety of operation was no longer a question, and
it was acknowledged to be distinctly a branch of surgical work.
There was a parallel between the tubes and the appendix, and
the pathology of the appendix was the same as that of the Fal-
lippian tube.

With regard to this wonderful power of Nature, Dr. Hoff-
man said that much of our surgery was done to cure the fail-
ures of Nature, and this was particularly true in the case of
the appendix. The conditions about the head of the colon
were such as we should not tolerate in any other portion of the
body. If they were in the duodenum, the surgeon would inter-
ference at once. Why should it be allowed to remain in one place
and removed in another?

We knew the reflex troubles that adhesions of the tubes and
ovaries might cause. We might have any number of reflex
symptoms. These same conditions were found in appendicitis.
If adhesions of the bowel would cause trouble in the neighbor-
hood of the duodenum, they would also cause trouble in the
region of the ceccum. It was no more surgical sense to leave
them in one place than in another.

Dr. W. Easterly Ashtom remarked that the theory that
every case of appendicitis was an infectious case was a long
step toward a knowledge of its pathology. No matter what
might be the exciting causes, all these inflammations must be
accepted as due to infection. The appendix was normally oc-
cupied with fascies in a more or less fluid state, and it must
therefore contain bacteria, so that any existing cause of inflam-
mation must at once be followed by infection. It had been
demonstrated that it was not necessary to have perforation or
even ulceration of the wall of the appendix or intestine to permit
migration of bacteria. This had been shown by constricting the
intestine of a rabbit with a rubber band, when, as soon as
stasis was produced, bacteria migrated. It had been further
shown that these bacteria under normal conditions produced no
trouble, but when there was any interference with the circula-
tion of the appendix or any want of integrity in its wall, these
bacteria not only penetrated the tissue, but perforated the wall
completely and escaped into the peritoneal cavity. All these
cases, no matter how mild, were infections. The fact that
the appendix was a rudimentary and unused organ was a con-
stant predisposing cause to attacks of inflammation, for we
knew that the retrograde changes occurring in an unused organ
made it especially susceptible to inflammatory attacks.

Again, the anatomic position of the organ rendered it
liable to dragging and strangulation. Situated as it was at the
head of the colon, with a small mesappendix and a single
arterial supply, distention of the large bowel or ileum would

He believed that in time all of us would agree that in appendicitis we were dealing with a septic affection, and when we did agree to this, then the knife would be used in all cases so

The President asked Dr. Morris how long he thought it necessary that the septic process should exist before we might have secondary abscesses? This question had come up in the pathological society on the presentation of the specimen of abscess of the liver which had been shown. It had been held by some that the abscess of the liver had probably not been due to the diseased appendix, because it had occurred within five days of the appendix trouble. He had seen three cases in which secondary abscesses had occurred within three days.

That these cases of appendicitis were infectious had been demonstrated by the large number of specimens shown.

Dr. Morris said that it was not safe to assume that any particular case of chronic intestinal indigestion was due to the appendix, unless on palpation we could determine that the appendix was probably the center from which the trouble proceeded. In most patients it was not difficult to palpate the appendix. He did not know what proportion of cases of intestinal indigestion were due to chronic infection of the appendix, but he knew that some were, and these should be subjected to proper treatment, which he believed to be surgical.

With regard to temperature, as he had stated, his impression was that high temperature at the outset usually occurred with mixed infection or streptococcal infection. He thought that the results of such infection were apt to be confined to the vicinity of the appendix for the first few days. With the insidious infection with the colon bacillus we were apt to have a temperature of 100° with a pulse of 120. Such a condition was more serious than a temperature of 105° with a pulse of 120. When the vital signs fell apart, we must look out. The general practitioner could not tell a priori whether a patient was to be entirely well or entirely dead in three days from the beginning of any attack of appendicitis. This could not be determined in advance, because the extent of the invasion of infection in any given case was not to be estimated. Our surgery had been making progress. If we could not show physicians by our surgery and our statistics that these patients ought to be operated on, we should not operate. He believed that to-day, however, we had an almost perfect operative technique in dealing with most forms of appendicitis.

Dr. Laplace believed that no two patients would react alike to the same infection. The speaker also believed that, but, if the temperature was high, we were apt to have a mixed infection or infection with streptococci. That he had determined by cultures from cases where the temperature had been high. All the points brought forward had been pretty well proved by his work before being presented.

Dr. Roberts asked in regard to the evidence of neuritis. This had been found in the direct examination of the nerves. These specimens had been examined by his pathologists and the evidences of sclerosis found. He had had one case where he had operated for a stump that had been left. The patient had suffered with neuritis, chronic constipation, and digestive disturbances, and had been an invalid for a long while. He had removed the stump, and the patient had made an excellent recovery. The bowels moved regularly; he was free from pain, and had gained in weight. Another gentleman had been compelled to give up his work as a professor on account of irritation in the fibrous remains of an appendix. This had been removed, and he had returned to his normal condition. A physician who had been a nervous, dyspeptic individual for many years had come to him with an appendix which had lost much of its structure. It had contained a few fibers of sclero.

He had avoided the question of operation because it was such a large one. As regarded his own statistics, he felt inclined, he said, not to quote them, for it would savor of boasting. He said, however, that in a pretty large number of patients operated on while infection had been limited to the appendix, and in the interval between acute attacks, he had had no deaths and nothing which had seemed to point to a bad result. He could not look forward to death in a case of this sort. Surgeons had developed an operation which was less to be feared than a single attack of appendicitis.

He had never seen catarrhal appendicitis. He had operated in cases where this diagnosis had been made, but he had never seen the affection. There was no doubt that catarrhal inflammation of the mucous membrane might occur, but he doubted if it ever gave rise to symptoms.

He believed, with Dr. Price, that it was better to do a pretty radical operation when we started in to remove the infected mass. He did not feel like leaving such a mass after having looked at it. His statistics, which would be published before long, would give an analysis of his results. We saved most of our badly infected cases to-day. Cases in which he thought, a short time ago, the mortality rate would have been fifty per cent., he believed would now give a mortality of less than ten per cent. These were the cases with pus, wide infection, and peritonitis.

As Dr. Ashton had said, bacteria might be present and no trouble arise until an affection atrium occurred, when the bacteria at once migrate. This might be caused in various ways; for instance, dislocation of an appendix from its particular position was very common. The individual might be struck by the elbow of a friend, or in certain manipulations the appendix might be displaced. It might not go back to its original position; it might be twisted on its mesoappendix. Its contents were locked in, and there might be a little discomfort, lasting a few hours. All at once bacteria would begin to migrate because the mucosa had undergone necrosis from twist pressure. This dislocation of the appendix was very common, and was usually a matter of no importance to the patient. He also believed, as Dr. Ashton had said, that the appendix was more readily attacked by bacteria because it was a rudimentary structure, just as some wisdom teeth were more liable to decay on this account.

As to the length of time between the beginning of infection and the occurrence of liver abscess, he could not say. He could only say this, that within forty-eight hours of the beginning of an attack of appendicitis he had found thrombi in the veins of the mesoappendix which could have caused the beginning of a liver abscess on that day. He did not see why there might not be abscess of the liver within two or three days of the beginning of an attack of appendicitis.

Miscellany.

Inflammation of the Parotid Gland as a Complication of Pneumonia.—The Archives cliniques de Bordeaux for January publishes an article on this subject by Dr. J. Hobbs in which he
MISCELLANY.

sits that among the complications which are but rarely seen in pneumonia parotiditis certainly has its place. If we refer to special works, to Grisolle's 'Traité de la pneumonie,' for example, we see that this author gives only a very short chapter to it, and insists on its exceptional character and its almost fatal tendency to suppuration. During the last few years this question, from the bacteriologist's point of view, has come up again, and several authors have occupied themselves with the subject, and have arrived at the conclusion that it is a question of pneu-

mooccous origin, the pneumooccous having been found by them in the pus of the parotid abscesses.

In these cases acute parotiditis occurs suddenly as the fever diminishes in pneumonia, and, after inflammation characterized by redness, swelling, and a sensation of false fluctuation, there is formed in twenty-four or forty-eight hours at the most, an abscess which it is necessary to open freely in a very short time.

When a bacteriological examination has been made it has been ascertained, sometimes on gelose tubes, sometimes on plate cultures, that the pyogenic agent is the pneumooccous and this important result became undisputable when the authors could, by direct inoculation with the pus in a mouse, reproduce in that animal a true reaction of the pneumooccous, a

generalized pneumooccous.

The explanation of suppurring parotiditis thus becomes easy, and we should rank it among the extra-pulmonary tendencies of the pneumooccous, along with endocarditis, meningitis, and otitis, of which M. Netter has demonstrated the distinctly pneumooccous origin. But the results may not be accounted for in this way, says the author. Parotiditis occurring during the course of the disease, at the decline of the fever, or even during convalescence from pneumonia, is not inevitably destined to suppurate; the whole thing may be limited to a hard and painful tumefaction, more or less resisting pressure on palpation, giving also a sensation of false fluctuation and becoming completely resolved in a certain length of time, without which intervention (incision or puncture) will be necessary.

The author relates several cases; among them the following, which had come under his own observation: The patient was a man, forty-one years old, who entered the hospital on August 31st. He stated that four years before he had received a violent shock in the right thoracic region. The day after his entrance into the hospital the fever was high, there was considerable dyspnea, and the temperature was 102° F. An external examination of the chest revealed nothing abnormal and the ribs were not fractured. On percussion, a noticeable dullness to the right and behind was found, the thoracic vibrations were exaggerated. Auscultation in the same region revealed a crepitant râle, there were characteristic rust-colored spouts, and the patient was very weak. There was no albumin in the urine.

On September 24 the temperature was 102° 8, and the patient was very delirious; the stethoscopic symptoms were somewhat modified. A very intense tubal soufle was found in the lower two thirds of the right lung, and a few crepitant râles were again heard. On the 4th the temperature was 104°, and the condition was the same. On the 6th, the soufle was not so loud, expectoration was more abundant, and the temperature was 106° 6. On the 8th the patient's condition was a little better, and the urine was abundant. Auscultation revealed very numerous subcrepitant râles in the lower half of the right lung; percussion, which was very painful behind, showed dense dullness. The temperature was 102° 2. The patient's face had a pinched look; he did not eat and complained of an intense thirst. The expectoration was always abundant, but it had lost its viscid consistence and its discoloration; it was now sero-

purulent. The temperature was 102°. On the 9th the patient expectorated pus. Percussion showed a zone of dullness behind and to the right, in the lower third, over a surface a little larger than a five-franc piece; at this point a true gurgling and an exaggerated resonance of the voice were ascertained. The tempera-

ture remained at 102° 2, and the patient's general condition was not ameliorated. Further, he expectorated constantly, especially in the morning, as in the case of a true vomica. It was now the twelfth day, says the author, and all these symptoms pointed to the existence of an abscess following pneumonia. On the 13th the local condition of the lung was becoming amelio-

rated; expectoration was less abundant, the dullness was less extensive, and the cavitary symptoms had lost their distinct-

ness. On the 14th the patient complained of pain in the left parotid region. At this point a tumefaction invading the mas-

ter in front and tending to extend below the angle of the jaw was found. Here the skin was red; on palpation, which was very painful, there was a sensation of profound resistance to pressure. Examination of the buccal cavity did not show anything in particular. On the 15th the pain was again intense, and the lowering of the inferior maxilla was almost impossible. The skin was red and hot. On palpation, it was thought that there was fluctuation. The temperature was 100° 8. On the 16th the tumefaction had greatly diminished; nevertheless, a puncture was made with Straus's syringe, which did not give a drop of liquid; meanwhile the author started cultivations in two gelose tubes. At the end of four days there was no trace of a colony. On the 18th, the tumefaction had completely disappeared and the patient began to eat. Convalescence in this case was particularly long and marked by icterus which lasted nearly two weeks. At this time the patient had alimentary glyco-uria and there was albumin in the urine. The treatment which was carried out during the entire course of the disease was essentially tonic and directed, in the beginning, to antispis of the digestive canal. Cachets containing eight grains of benzo-naphthol were given successively, one each day; which was followed by salol in doses of thirty grains a day. Croscote (in potions and inhalations) was also administered for the pulmonary abscesses, which, however, had perfectly run its course. On October 13th the patient left the hospital completely cured.

What significance, says Dr. Hobbs, should be given to this case? What is the pathogenic of parotiditis aborted in some degree, of a fluxion of the parotid gland? Should it be ranked with suppurring parotiditis due to the pneumooccous, or should it be completely separated from the list of the extra-

pulmonary pneumooccous causes? The latter opinion, says the author, is too exclusive.

Without doubt, he says, it was not here a question of spe-

cific pneumooccous infection of the parotid gland, since in the cases mentioned there had not been suppuration, and suppur-

ation, so to speak, is the pathognomonic characteristic of the metapneumonic complications. Further, the bacteriological examination had given negative results. The objection may be raised that inoculation of the mouse had not been made; that, surely, was a weak point, but the sole fact that the puncture had given no inoculable bâtrid removed from this objection a part of its value.

The author was led to connect this inflammation of the pa-

rotid gland with an aseptic glandular alteration, and here, he says, he could not but accept the division made by Claisse and Duprâ in their work, 'Les Infections salivaires.' These two au-

thors had to distinguish the canicular alterations, which are always septic and suppurring, from certain aseptic glandu-

lar alterations depending on a general cause, occurring as
dystrophia following serious poisoning or an infectious disease.

From an anatomical point of view this glandular dystrophia can only manifest itself by a simple modification in form of the glandular capsule and of their cells. In one case Clausie and Dupré observed necrosis with destruction of the epithelial cells and of their nuclei.

From a clinical point of view, it is here a question of a common and simple infection, occurring during pneumonia, which was especially serious in this case, putting the patient in a condition of the least resistance. This inflammation of the parotid gland, which is so remarkable for its short duration and its easy resolution, may be compared to the parotid tumefaction described for a long time as occurring in menstruation, in bennethria, in gripe, or even in gout, and distinguished from those serious forms of parotiditis, constantly suppurating, where the pneumatic cells are found in pneumonia and Eberth's bacillus in cases of typhoid fever.

The American Academy of Medicine.—The twentieth annual meeting will be held at Johns Hopkins University, Baltimore, on Saturday, May 4, and on Monday, May 6, 1895, under the presidency of Dr. J. McFadden Gaston, of Atlanta, Ga. The preliminary programme includes the following papers: Expert Testimony, by Dr. Henry Leffmann, of Philadelphia; Hospital Management, by Dr. W. L. Estes, of South Bethlehem, Pa.; The Proper Teaching of Physiology in the Public Schools as a Means of Preventing Intemperance and Venereal Disease, by Dr. De Lancaster Rochester, of Buffalo; The Problem of Dependency as Influenced by the Chinese in America, by Dr. W. F. Southard, of San Francisco; What Agencies conspire to check Development in the Minds of Children? by Dr. Madison Taylor, of Philadelphia; How to Avoid the Dispensary Abuse, by Dr. Emma B. Cullerton, of Boston; Contract Medical Work and Fees, by Dr. Charles P. Kuopp, of Wyoming, Pa.; What shall we do with our Alcoholic Inebriates? by Dr. J. W. Grosvenor, of Buffalo; Life Insurance in its Relation to one of the Dependent Classes, by Dr. E. O. Bardwell, of Emporium, Pa.; Some Results of Competitive Medical Charity, by Dr. George M. Gould, of Philadelphia; Criminal Anthropology, by Dr. E. V. Stoddard, of Rochester; The Increase of Insanity, by Dr. Gershon H. Hill, of Independence, La.; A Perfect Consultation, by Dr. L. Duncan Balfour, of New York; An Analysis of the Reports of the Examinations by the State Boards of Medical Examiners, by Dr. Perry H. Millard, of St. Paul; The Limits of a Physician's Duty to the Dependent Classes, by Dr. James W. Walk, of Philadelphia; The Economic Aspect of American Charities, by Dr. Bayard Holmes, of Chicago; and Is our Financial Relation to our Patients and to the Community the Best Possible? by Dr. Woods Hutchinson, of Des Moines. Dr. Learts Connor, of Detroit, will read a paper the title of which will be announced.

The Regression of Certain Goitres after Exposure of the Hypertrophied Thyroid Body to Air.—The Province "ifiliale for January 26th contains an article on this subject by M. L. Bévard, who relates the following case which had come under M. Poncelet's observation, and showed very plainly the favorable results that may be obtained with this treatment, which, he says, is easy for the surgeon to practice and painless for the patient: The patient, a young man without any previous history of disease, presented an enormous two-lobed goitre. The affection had shown itself four years before in a progressive increase in the size of the neck, and this had gone on imperceptibly since then, without any inflammatory attacks and without causing any serious functional troubles. However, for several months the patient had complained of dyspncea, which became more and more marked. At the examination it was ascertained that the general form of the neck was like that of the trunk of a cone very broad at the base. There was hypertrophy of the lateral lobes of the thyroid body, which were represented by two pyriform masses from nine to ten centimetres in height, of a homogeneous consistence, and resisting pressure; there was no appearance of a hard core or of cystic points, and no notable increase of the median lobe. There did not seem to be any retrosternal prolongation. The skin over the tumor was free from adhesions, but the tumor, on the contrary, followed all the movements of the larynx. There was rhythmical swallowing keeping time with the beating of the pulse, without true expansion. The external jugular was deviated to one side and slightly dilated; the anterior jugular was distinctly outlined, as well as the extensive anastomosis which united it to the external jugular. The vascular-nervous pleura of the neck was concealed behind the two hypertrophied masses and communicated its throbbing to them. The eyes were slightly brilliant, without exophthalmia; there was no palpitation, or tachycardia, or tremor, and the voice was soft. There was no myxedema or change in the character, and the concepitive faculties were intact. There was a slight plumpness of the face, with rather marked anemia. An examination of the urine showed nothing, and the general condition was good. The cervical circumstance at the level of the most prominent part of the tumor (three centimetres above the sternal notch) was forty-two centimetres.

The patient was put under the influence of ether and a longitudinal median incision was made in the subhyoid region, involving all the soft parts as far as the capsule of the thyroid. A fleshy goitre, buried with large veins, the network of which covered the anterior surface, was found. There were no outgrowths, only two lateral masses. After incision and refraction of the capsule, displacement to the outer side was attempted; but, whether because of the extreme softness of the trachea, or because of the presence of a retro-thyroid ring, as soon as the right lobe crossed the lips of the incision, a subcutaneous attack was immediately produced. Dislocation of the other lobe only aggravating these symptoms, the physician contented himself with isolating the neighboring tissues on the edge of the tumor, which was put back in its former place and the wound left open under the dressing. All dyspncea disappeared. There was no hemorrhage at the time or afterward. At the end of forty-eight hours several clamps were removed and the dressing, which was saturated with a great deal of serosity, was changed. During the following days the patient complained of a sensation of tension about the wound, but he no longer felt any functional inconvenience.

Eleven days after the operation the neck was again measured and the circumference was found to be thirty-eight centimetres, a diminution of four centimetres. A month later the measurement was thirty-six centimetres, and two weeks after that it had gone down to thirty-three centimetres. The wound where the incision had been made was almost completely cicatrized and the ugly shape of the neck was so very much modified that no trace of the deformity could be seen unless the shirt collar was very much opened. Above all, the normal tone of the voice had returned, also the patient's ability to walk rapidly and even run without inducing palpitation and suffocation.

How, says the author, is this to be explained? No more than in the case of ex-thyreopathy is it possible to formulate a complete and logical theory. It is on observations, especially clinical, he says, of general atrophy of goitres after unimportant interventions involving the thyroid body or the capsule that M. Jaboulay based his new method, and, according to him,
MISCELLANY.

From Lastly is all as man isulated spirit averages, utterly good, ing the B6rard, vagus on intervention is rendered impossible or very hazardous because of the nature, the size, or the connection of the goitre.

In young patients the tumor is always buried in the network of enormous veins, without, however, threatening suffocation by downward retrosternal prolongation. This type of goitre may exemplify two particularly frequent conditions. It may spread on the surface in front of the laryngo-tracheal tract and on the vascular-nervous plexus of the neck, and thus occasionally cause dyspnea on exertion and symptoms of irritation of the vagus and of the cervical sympathetic; or it may send a unilateral or bilateral prolongation behind the trachea, which often does not manifest itself by any serious symptoms in the ordinary conditions of life, but produces imminent suffocation on the least attempt at dislocation or of moreclement of the tumor.

Simple exposure to the air has, beyond all dispute, says M. Bérard, the following advantages: Absolute harmlessness; complete absence of hemorrhage; preservation of the connection of the thyroid body with the trachea; and, finally, the possibility of effecting, without the aid of general anesthesia, simple insensibility of the superficial surface with methyl chloride or with cocaine. Accidents with anesthaesia are not the least of the complications in surgical intervention in cases of goitre.

A Plea for Old-fashioned Diet.—In the Australian Medical Journal for December 20th, Alexander Lewers, M. R. C. S., of London, contributes an article on this subject in which he says that, if we take all the foods and beverages now procurable at any respectable chemist's at their face value, a man might go from the cradle to the grave without any digestive functions at all. It is all done for him in the laboratory. Since the days of Liebig's extract, he says, we have had a bewildering vista of artificially prepared foods opened up, and the practitioner of-to-day suffers rather from an embarrassment of riches.

His personal experience of these medical luxuries, he says, has been somewhat disheartening, although the preparations are all that they purport to be, but the difficulty lies in inducing the patients to take them. It is not implied that the researches in this direction have not been productive of much good, and promising much that will probably be better, but the spirit of ultra scientificism, says Mr. Lewers, seems to be abroad to the detriment of common sense observation. There is a growing tendency to lean on the deductions of the laboratory, to accept laboratory tests as to the behavior of drugs and foods, and to trust less and less the results of what happens under our own eyes. A glass test-tube and a bottle of hydrochloric acid, says the author, do not, and never will, represent the human stomach under any condition, and even theories formulated on the evidence of minute quantities of gastric juice abstracted from the stomachs of uncomplaining patients are utterly worthless, as they represent but a momentary phase of ever-changing conditions. The practitioner must remember that in practice we have to deal with individuals, not with averages, and, just as there are not two human faces exactly alike, so there are no two human stomachs precisely similar.

And this fine dieting is not only impossible, but wrong in practice, and the knowledge of the average is of use to us just to that degree that we can determine how closely the patient approaches to or departs from it. The diet in typhoid fever, says Mr. Lewers, may be chosen for illustration, as the problem we are interested in is both simple and difficult,—first, because the general principle is so clear; secondly, because the application of that general principle to the individual requirement is difficult. In typhoid fever the whole gastro-intestinal tract is profoundly affected, and the diet must be as far as possible fluid and not irritating.

In a recent paper, the author, Dr. Springthorpe advocates the exclusive use of a malt extract, and gives a series of cases which show no worse and no better results than those on a more varied diet. It may be urged, he says, that a typhoid-fever diet should be varied rather than monotonous, and that in future much of the wasting of this and other diseases may be obviated if we can only suit our variations to the particular patient. For the staple article, milk still holds the first place. There is the objection, however, that it is frequently passed undigested. In this case it may be diluted with lime-water or barley-water or, if necessary, peptonized. At the same time the patient's attitude toward it must be observed. If there is a pronounced distaste for it, and it is continued to be forest upon an unwilling stomach, it will in all probability be passed undigested, whereas if it is given judiciously and in proper quantities there will rarely arise any need for interference. Given intelligently, it admits of being mixed with soda-water and stiffened with gelatin, warmed or iced, sweetened and flavored with a dash of tea, coffee, or cocoa, so that the monotony may be effectually disguised.

The first of the classical variations is beef tea. This is often an unpalatable and sickening concoction, and it is not to be wondered at that patients do not appear to derive much benefit from it. Mr. Lewers himself prefers it made from the fresh beef to any of the patent essences, although these may serve occasionally. He generally directs that the stock should be flavored with vegetables, for in this way it is rendered more palatable and more nutritious. It should form into a gelatious condition when cool, and a few spoonfuls of this may be taken in place of a drink; when given as a drink it should be somewhat diluted. An objection is made that beef-tea is relaxing and increases the diarrhoea. This is true to some extent, but, as constipation is frequently a prominent symptom in typhoid fever in Australia, says the author, the objection does not hold good, and in any case the effect can easily be judged. Giving concentrated meat essences or extracts, even if they are alleged to be pre-digested, is useless if not absolutely pernicious.

Veal broth or chicken broth may also be advantageously introduced and used in the same way. Mutton broth is bad, as it is difficult to free it from fat, and it is always apt to produce nausea and even vomiting. Thin arrowroot and maize, judiciously employed, are valuable additions to the diet. Gruel, well strained, may be allowed where diarrhoea is not a prominent symptom. A new-laid egg may be beaten up with a little brandy and given occasionally.

With regard to beverages, says Mr. Lewers, aerated water and lemonade are most useful. Barley-water is insipid, but if the patient likes it there is, unquestionably, some slight nourishment to be derived from it. Lastly, pure water is an article too often forgotten or altogether withheld. It is difficult, he says, to get untrained nurses to administer water to a fever patient, but we should always bear in mind that at least half the diet in typhoid fever should be water, although the proportion must be determined in each particular case. Wine is totally unsuited to
Rowing as an Exercise.—The last number of the Aselepiad contains a lecture by Sir Benjamin Ward Richardson, entitled Health and Athletics, in which he says:

"Rowing, of which university men are so fond, is of all exercises the one which affects respiration. You will see a crew that has not yet been trained go out for active exercise, and as they get into the full swing of the work you will notice, if you are careful, how powerfully the breathing is affected. The breathing, you will see, is rapid; there is a sort of blush pallor in the lips and face, and even when the act of rowing is stopped there is an out-of-breath condition which is felt, more or less, by all who have been doing the same work. Of course there are always differences in different rowers according to the build of the body. The man with a large chest and short body, and the tall man, the man who by a spirometer can show from two hundred and fifty to three hundred cubic inches without fatigue, will be infinitely less breathless than the man with a small chest and short body, and who can only blow two hundred to two hundred and fifty cubic inches; but more or less all will suffer, and the great danger of rowing lies in injury done to the respiration in the first instance. If I were to select from a body of young men, promiscuously brought together, those who were best for a rowing match, I would, by proper measurement of the breathing power, of the height of the body, of the size of the chest, pick out almost without question those men who would make, in the end, the best crews, although at the time not one of them had become trained to rowing practice; and this is, I think, what ought to be done in the selection of crews for great competitions, since it is very bad for a young man even to train into a practice which by excessive exercise shall impair the function of the lungs. I do not say this from any prejudice, and I do not wish to exaggerate in the least degree. The disease emphysema—that is, rupture of the air vesicles of the lungs—which some think they have noticed as consequent upon rowing, I can not say I have ever seen, and it is but honest to add that I have known an improved development of the breathing organs and of the capacity of the chest induced by moderate rowing. What I have seen, and what I would warn against, is an effect of rowing which shows itself in a persistent difficulty of breathing during the exercise, and which is followed by some shortness of breath in other efforts, such as walking and riding, playing at tennis or cricket, and such like exertions. Rowing, moreover, when it affects the breathing, is liable, secondarily, to cause disturbance of the circulation. The position of the rudder in the boat is peculiar. His lower limbs are to a considerable extent fixed; his body is bent forward and then strongly backward, the chest being kept in full tension. During these acts there is a considerable strain thrown upon the valves of the heart. The blood which has to course over the arteries from the heart must ascend before it makes its way anywhere over the body; ascends over what the anatomists call the aortic arch, and be prevented from going back into the heart on the left side by three valves, which allow the blood to come forth from the center, but which, falling down, check it from being returned. But in the motion of rowing with the lungs charged with air, the blood rising through the arch is, in a sharp degree, thrown back upon the valves, much as occurs in water falling back on a tap, to which we give the name of the water hammer. So I have observed that in a man who has been briskly rowing the second sound of his heart, which is produced by closure of the three valves, is often accentuated, owing to the sudden pressure exerted by the column of blood. Now this is a very considerable strain. By the influx of blood the heart is made to work more laboriously; it has an extra pressure put upon it; it is quickened in its action, and the great elastic blood-vessel, or aorta itself, is unduly distended. So in rowing men there occasionally follows disturbance of the heart as well as of the breathing. The heart becomes unduly large and overactive, a state for which, in order to obtain recovery, the injured person may have to be in a recumbent position for several months, and from which possibly he never entirely returns to health, but has an excitabil state of the circulation when he is subjected to any particular strain or mental worry. Rowing, therefore, although a fine exercise, requires to be carried on with some prudence, and while I have not a word to say against it, but indeed very much enjoy the sight of it in a good contest, it is, I should like to intimate, an exertion which should never be persevered in if the signs of embarrassment, first of the respiration, and secondly of the circulation, are clearly felt and detected by those who practice it; for I doubt if there is any going back to health, in the strict sense of that term, when such signs are definitely pronounced and for a long time maintained."

The Late Dr. Alfred L. Loomis.—At a meeting of the New York Pathological Society held on February 13, 1895, the following resolutions on the death of Dr. Alfred L. Loomis were adopted and spread on the minutes, and the secretary was requested to send a copy of the same to the Medical Record and the New York Medical Journal for publication:

Whereas, It becomes our duty to announce the death of Dr. Alfred L. Loomis, a former president and for a long period a cherished member of the New York Pathological Society, therefore be it

Resolved, That this society desires to place on record its high estimation of those qualities for faithful, persistent, and skillful work which characterized all his efforts during more than a quarter of a century of active membership.

Resolved, That his minute and painstaking study of clinical facts in connection with pathological lesions, and his logical demonstrations of their practical significance, constantly proved his eminent fitness as a safe teacher and his high and rare qualifications as a leading authority.

Resolved, That his example of indefatigable labor in this society, his ever-ready willingness to advance its best interests by valuable contributions from his large experience, and his earnestness of purpose in extending its usefulness are grateful reminiscences of his unselfish act, of his conscientious regard of duty, and of his earnest devotion to the highest aims of pathological research.

[Signed] GEORGE F. SHAFRY, M.D.
    EDWARD G. JANEWAY, M.D.
    JOHN H. HINTON, M.D.

The New York Academy of Medicine.—At the last general meeting, on Thursday evening, the 21st inst., the special order was a discussion on Amputations; a Statistical Study of Seven Hundred Cases from Eight Hospitals of this City. At the next meeting of the Section in Laryngology and Rhinology, on Wednesday evening, the 27th inst., a paper entitled 'The Treatment of Laryngeal Tuberculosis by the Appli...
The Remote Results of the Removal of the Uterus and of the Ovaries.—Dr. Ernest W. Cushing, of Boston, contributes an article on this subject to the Boston Medical and Surgical Journal for February 14th, in which he remarks that the question in regard to the removal of the uterus is a very important one. It is a subject which it is well to consider, he says, because it is one of the latest developments of surgery. It will be admitted now that the remote results of the removal of the uterus are good if it can save a woman from death by cancer, and about half of the patients are saved for three or four years, and something less than that are saved permanently. The question of removal of the uterus for fibroids has worked its way against opposition. Where the mortality used to be sixty per cent, it is now less than twenty per cent., and the best results give not over from six to ten per cent.; so that the removal of the uterus for myoma is now as well established as the removal of the ovary for ovarian tumor. Its increased safety and its advantage to suffering women are continually forcing surgeons to operate in cases where they would not have done so a few years ago; that is, the increasing knowledge of the bad effects of leaving myomata, such as complications which finally ensue from pressure on the ureters or on the intestine, from degeneration of one kind or another, from long-continued hemorrhage, from complications of salpingitis, etc., have wrought such a change of opinion that surgeons are much readier to remove the uterus than they were a few years ago. Some, says the author, are going so far as to say that they will remove a fibroid of the size of a fist in order to guard against future growth and accidents. Now, however, by the development of surgery, it is found that by vaginal hysterectomy a small fibroid can be removed with ease and with practically complete safety. If, says Dr. Cushing, we can remove the little fibroids essentially without danger, there will not be any large fibroids, just as there ought not to be any large ovarian tumors in civilized communities if it is safe enough for that, the question of removal of the uterus for prolapse arises. The difficulties of this operation, and all the different things that have been tried, are known. Now it is done by many, and laid down as a proper thing to do.

With regard to the remote bad results of the removal of the uterus and its appendages, says Dr. Cushing, the charges against it are, in the first place, the production of insanity; in the second place, the production of obesity; and, in the third place, loss of sexual desire. In regard to insanity, he says, it is a fact that various gynecological operations are followed sometimes by insanity. The removal of the uterus is done for certain very definite indications. It is done for cancer, fibroids, or prolapse, or by the intention, when the tubes are badly diseased and the interior of the uterus inflamed from gonorrhea, etc., of getting rid of the whole trouble at once; therefore, there are certain diseases which are, so to speak, mechanical; at any rate, not nervous. They can be seen and felt and demonstrated, and the patient knows what she is cured of after the operation.

In regard to the removal of the ovaries and the tubes, there are several different conditions. If the patient's tubes and ovaries are diseased, full of pus, and perhaps as large as potatoes; if there is high temperature, with chills, and the patient is likely to die, then they should be removed. What the remote effects are is of no consequence; the patient must be got out of immediate danger. Then comes the question of how much the patient is cured. A certain number of them continue to suffer, and it is partly owing to conditions which could not be helped at the time. There are different complications, and they require the operation to be done over again, and a great deal of that work, says the author, is gradually being done. Sufferings are caused by the fact that there is still some trouble which may require another operation.

There is another class of cases where there are cirrhotic ovaries. The great trouble is dysmenorrhea. The patient suffers for years and her nervous system is broken down; it is the result of the long-continued injury to the nervous system and must not be laid up against the operation. There are some cases where the ovaries are removed for dysmenorrhea for which there is a real anatomical basis, such as inflammation of the ovary, suppuration of the ovary, inflammation of the tube, or adhesions; these are removed for disease, not for dysmenorrhea. They should be removed, says Dr. Cushing, and, if the patient is not entirely cured, it can not be helped.

Another cause of suffering that many attribute to disease of the ovary is varicocle of the pampiniform plexus. It is apt to give rise to various sufferings, such as pain, pressure, and nervous and mental symptoms similar to those caused by varicocle in men. There are cases where the ovaries are removed for other kinds of nervous symptoms; for hystero-epilepsy, epilepsy coming on at the menstrual period and at no other time. Cases of insanity where the ovaries have been removed, with the result, in a certain proportion of cases, of curing the insanity, have always been, so far as the author knows, cases of anatomically demonstrable tubal or ovarian disease. The care here is not on account of the removal of the ovaries, but on account of the removal of an inflamed and irritating mass, and it is possible that it might be something else than the ovary, and the removal of it might have the same effect. There are other cases where the ovaries have been removed for nymphomania and masturbation with the patient approaching idiozy. In regard to this whole subject, says Dr. Cushing, there is at present a sort of reaction in surgery. Dr. Polk, at the meeting of the Congress of American Physicians and Surgeons, called attention to the fact that removal of the appendages, which brought about the change of life, caused not only the temporary symptoms, flushings, and various nicheris which women have to go through with some time, but it also brought about atrophy of the vagina and genitals in some cases, and a loss, in other cases, of sexual desire and feeling, which certainly is a serious matter. Dr. Goodell had also, says the author, started a paper in which he set forth the various woes and evils which might follow the removal of the appendages. The author's experience, however, has been very different from that of Dr. Goodell. He has found that in the vast majority of cases the ability, under proper circumstances, to have as much sexual feeling as the patients previously had is not impaired. His experience has been that the removal of the uterus has no more evil effects than the removal of the appendages alone, and that the removal of the appendages alone has, in itself, under very rare circumstances, caused a loss of sexual feeling—that is, of the capacity for sexual orgasm—which, he says, is to a certain extent to be regretted; but those instances are very rare. If we were to take a hundred women whose ovaries have been removed, he doubts very much whether we should get a much greater proportion who gradually lost their interest in sexual matters than in an equal number whose ovaries had not been removed.
The phenomenon which has attracted most attention in the pathology of the blood in recent years is that of inflammatory leucocytosis. That this delicate element of a fluid tissue, the leucocyte, should be able to muster within a few hours in quadruple or even sextuple numbers in the blood, is truly a matter to excite admiration or even incredulity.

It is the part that leucocytosis may play in the production of immunity which lends to the subject to-day one of its chief interests. That large numbers of these cells showed a tendency to surround all sorts of foreign bodies in their vicinity was a fact eagerly seized upon by adherents of the cellular theory of immunity, and soon became for them a chief factor in argument.

Naturally, investigation was first directed to the most pronounced example of this condition offered by disease, so that to-day more is known about leucocytosis in pneumonia than in any other malady. Beginning with the interpretation of the crusta phlogistica by Pierrry (1) in 1839, and the first formulated theory of leucocytosis by Virchow (2) in 1871, in the last ten years a score of observers have been over the ground, and at present there is comparative unanimity in the interpretation of the variations of leucocytosis in pneumonia.

But the ready assumption of the phagocytic nature of leucocytosis by adherents of the cellular theory of immunity, and the evident importance of the phenomenon in the course and limitation of disease, elicited yearly new and varied theories of the origin and nature of leucocytosis.

Virchow’s theory of simple proliferation first appeared. He presumed that a new formation of leucocytes occurred through simple proliferation in the lymph nodes, in the swollen bronchial nodes of pneumonia, in the hypertrophied chains of leucemia, and through the general lymphadenitis of syphilis. He failed to explain, among other things, the failure of leucocytosis in pseudo-leucemia, in typhoid fever, and in tuberculosis.

Roemer (3) attributes leucocytosis to the action of products of tissue metabolism and bacterial life, especially to alkali-protein. These products, he believes, reach the blood and lymph from their point of origin in the tissues, and exert a direct chemotactic and formative influence on the leucocytes. The formative influence acts in the circulating blood, and produces an increased number of leucocytes by the method of amitosis. By chemotaxis the new leucocytes are drawn into general or local circulation. That chemotaxis plays a part in the phenomena of leucocytosis is generally admitted, but that amitosis has been demonstrated as the method of origin of polynuclear leucocytes is denied by most histologists (Riesler (4)). Roemer’s chemotactic theory stands, therefore, neither proved nor disproved.

Von Limbeck’s (5) theory of “exudation” is in partial agreement with Roemer’s. He believes that chemical bacterial products cause a reaction on the part of the tissues, with exudation and leucocytosis. This reaction, which is to be regarded as Nature’s effort at healing, is specially directed to the spleen, lymph nodes, and marrow, from which he holds the new leucocytes to be principally derived. Thus there are more leucocytes in the splenic vein than in the veins of the abdominal wall. Von Limbeck failed to prove that there were more leucocytes in the splenic vein than in other visceral veins; the relation between exudation and leucocytosis is not constant, and his theory does not explain hypoleucocytosis.

Since 1872 it has been known that the injection of curari into the blood caused a disappearance of leucocytes. Similar results were noted later after the injection of fibrin ferment, pus, peptone, etc. Finally, the same phenomenon was observed after injection of bacteria and their products (6). The great constancy with which the diminution precedes the increase of leucocytes impressed Lowit (6) with the idea of the essential character of this sequence, and led him to find in the impoverishment of the blood the cause of leucocytosis. The exact manner of the disappearance of the leucocytes he held to be an actual destruction or solution (leucocytolysis). The regeneration of the blood in hyperleucocytosis he referred to an increased activity of the blood-producing organs, the lymphocyte being the initial form in which the new cells reach the blood. Neither mitosis nor amitosis occurred with sufficient frequency in the circulating blood to account for the abundance of new leucocytes. During the stage of hypoleucocytosis Lowit proved that the diminution of leucocytes is general over the superficial vessels. He states that he found this diminution to prevail also in the central vessels, but the extent of his observations on this latter point he does not state. The numbers of leucocytes actually found in the central vessels, any comparisons he may have made with the normal numbers existing there, and the conditions under which he drew the specimens of blood, he does not report; but admits having found great variations in the condition of the central vessels. Schulz (7), therefore, finds in Lowit’s statements no proof that the leucocytes are not increased in the central vessels while diminished at the surface. Moreover, Lowit fails to explain sufficiently why the new cells to be found in leucocytosis are multinuclear, while maintaining that the form in which they are produced by the organs is unimuclear. Finally, at no stage after the intravenous injection of bacteria does he find in the blood sufficient evidence of recent destruction of leucocytes.

Biellianski (8) has recently offered some new suggestions as to the nature of leucocytosis, based upon a study of the morphology of the leucocyte in the different stages of pneu-

Leon. He believes that leucocytosis may be produced, first, by increased activity of the lymph nodes, as in syphilis and leucæmia. Second, it may be due to failure of development of lymphocytes into multinuclear cells. So there may be lymphocytosis without lymphatic hyperplasia. Third, leucocytosis may be due to the failure of further development of polynuclear forms and their consequent accumulation in the blood. In short, leucocytosis, according to Bieganski, is a result of the prolongation of the life history of leucocytes induced by bacterial products circulating in the blood. He calls attention to the sudden appearance of eosinophile cells and of blood plates after the disappearance of multinuclear leucocytes in pneumonia, and cites Zappert (9) and others to support the belief that eosinophile cells are older "fatty" forms of multinuclear leucocytes.

The proof of his theories demands the previous settlement of nearly all the questions now open concerning the leucocyte. That a noxious bacterial poison should exert a preserving influence on the leucocyte it is not natural to suppose. The condition of the blood in leucæmia is not generally regarded as a leucocytosis; while in pseudo-leucæmia there is much lymphatic hyperplasia without leucocytosis. The multinuclear leucocyte, as stated by many authorities, may either break up into blood plates or develop into an eosinophile cell, but it certainly does not develop indifferently into both elements, and it is still doubtful if it is the forerunner of either. According to various observers, the blood plates may be preformed normal elements in the blood (Bizzozero (10)), or broken nuclei of multinuclear leucocytes (Lilienfeld (11)), or globulin particles (Lowit (6)); and the eosinophile cells may be older forms of multinuclear leucocytes (9), or a separate order of cells developed from the eosinophile elements of marrow (H. F. Müller (12), Goldscheider and Jacob (18)); but all these questions are far from solution.

An examination of the foregoing theories reveals in their foundation a very considerable amount of surmise associated with a moderate amount of proof. The incompleteness of our knowledge of chemotaxis; the assumption that all kinds of leucocytes are developmental forms in one series and not representatives of three different series (H. F. Müller (12), Foster (13)); the very capricious behavior of the leucocytes under various physiological as well as pathological conditions; especially the sudden appearance, in hyperleucocytosis, of enormous numbers of adult multinuclear elements—all these considerations might well raise a doubt as to the validity of our knowledge of leucocytosis. In view of the contradictory evidence, Schulz explains that "the whole subject of the existence and meaning of leucocytosis is still "terra incognita," and demands extended experimental research." It was apparently this general view of the uncertain foundations of the subject that led Rieder (4) and Schulz (7) to maintain that no sudden increase in the sum total of leucocytes in the blood ever occurred in leucocytosis. As Rieder, at the close of his monograph, states this last view: "There is no definite evidence of an increased outpour of leucocytes from the blood-producing organs, still less of an increase of the same in the blood, nor of an abnormal gathering of wandering cells from the tissues. It must be regarded as much more probable that leucocytosis is not an increase of the sum total of leucocytes circulating in the blood, but only an abnormal distribution of those already existing in favor of the peripheral vessels." Schulz, examining the blood from peripheral and central vessels in dogs, guinea-pigs, and rabbits, was able to convince himself of the correctness of Rieder's hypothesis. During the stage of hyperleucocytosis in peripheral vessels he found no corresponding increase, and even demonstrated a decrease of leucocytes in the central vessels. Whatever may be said of his technique, which will be discussed later, at least an equal number of contrary results are necessary to disprove his position. The present study of the writer was intended to prove, by an independent series of experiments, the truth or falsity of the Rieder-Schulz theory. It was hoped by demonstrating the presence or absence of a change in the sum total of leucocytes in the circulating blood, to settle the question whether the present conception of leucocytosis is based on fact or upon unreliable experimental data.

Technique.—In order to determine the possible changes in the general distribution of leucocytes that may occur after intravenous injection of bacteria, specimens of blood were examined from the central vessels as well as from the peripheral veins, from which the estimation of leucocytosis is usually made. The microscopical examination of the organs was then demanded, to locate, if possible, the lodging place of the leucocytes found to disappear from the circulating blood after bacterial injections. Rabbits were chosen for the experiments because of the ease with which they are handled, and on account of their comparative freedom from physiological leucocytes. The experiments of Schulz were repeated a number of times as he performed them, and later an endeavor was made to eradicate some of the features of his technique that were deemed incompatible with accurate results. Accordingly, some of the animals were killed by breaking up the medulla; the abdomen was rapidly opened, and five or six specimens of blood were drawn, by as many "mixers," from the central vessels. This procedure consumed in Schulz's hands usually not longer than fifteen minutes. The writer's specimens of blood were drawn, through a fine needle puncture, in from five to eight minutes after the animal was touched, and no specimen was drawn after the blood pressure became so markedly reduced that the blood failed to spurt from the vein or artery. Several rabbits had to be rejected on this account.

The method used in estimating the leucocytes was the same as employed by the writer in a previous study of the leucocytosis of pneumonia (14), and which, though more laborious, has in his hands given more uniform results than has the acetic acid method. That the acetic-acid method proves extremely unreliable in the experience of others is well shown by some of Schulz's results, in which the estimates of the same vessels varied as much as two hundred and fifty per cent.

The Thoma-Zeiss erythrocentimeter was used, the blood diluted a hundred times in three-per-cent. salt solution
tinged with gentian violet, and the red cells were thus not dissolved. Changes in the number of red cells and blood plates were therefore regularly noted, and it was possible to detect appearances of the destruction of leucocytes by the media injected. An objection to this method is, of course, the comparatively small number of leucocytes actually counted. This defect was partly remedied either by drawing a double amount of blood into the pipette, making the dilution 1 to 50, or more frequently by using two counting chambers and counting a double field in each. The double field, though only partly inclosed by the lines of the Zeiss instrument, can be accurately followed without a mechanical stage, by counting over an extra quarter field on each side of the present body of four hundred squares. With a mechanical stage as many leucocytes can readily be counted as in the acetic-acid method.*

After drawing the specimens of blood, the liver, lungs and heart, kidney, spleen, and one femur were removed and hardenened for microscopic examination in various agents—such as alcohol, forty to ninety-seven per cent; Müller's fluid; Lang's fluid; one per cent. bichloride of mercury; formalin, two, five, and ten per cent. The best preservation was obtained from alcohol, eighty per cent., replaced in twelve hours by ninety-seven per cent. The further procedure with the organs will be described under the report of the microscopical examination.

Dry preparations of the blood were made and stained, with or without heating, by saturated alcoholic solution of eosin and methyl blue or Gage's hematoxylon. Of these dry preparations it may be said only that they showed the typical forms described by Okintschitz (15) in normal rabbits' blood, and the great preponderance of uninuclear elements commonly found in hypoleucocytosis.

The order of the experiments was as follows: First, the normal number of leucocytes in the central vessels was determined in rabbits killed by breaking up the medulla, as no sufficient data on this question could be found. Following this, the same vessels were examined, at intervals of five minutes to two hours, after injecting into the middle-ear vein 0.5 to 1.5 cubic centimetres of a three weeks' old broth culture of Bacillus pyocyaneus. The injection of this medium was found to reduce the number of leucocytes in the opposite ear vein progressively for at least three hours. Finally, in view of the very great disturbance of the circulation likely to follow destruction of the medulla and immediate failure of respiration, the effect of deep ether narcosis on the blood of the large jugular vein was determined, and all these experiments were repeated on rabbits thus anesthetized. To determine the effect of ether narcosis, the rabbit was rapidly bound to a frame and the internal jugular vein exposed by a few short incisions. The specimen of blood was then drawn from the vein and the animal immediately released. By completing this operation within ten minutes, the effects of cooling and exhaustion were practically avoided. At the end of a half hour the same animal was deeply etherized, and specimens were examined from the same vessel.

It will be seen from the preceding tables that during the stage of hypoleucocytosis a uniform diminution of the leucocytes can be demonstrated in all parts of the arterial and venous circulation. Even following, in general, Schulz's own procedure, but drawing the blood from the vessels rather more rapidly than he did, and avoiding much of the change resulting from lowered blood pressure and stagnation of blood in the large veins—factors which apparently disturbed his estimates—this uniform diminution of leucocytes will be still found, and an opposite conclusion to his must be reached. When, however, results obtained in etherized rabbits are compared, this contrary conclusion becomes indisputable. The leucocytes can be found neither in the arteries nor in the veins. Indeed, after a careful examination of Schulz's published tables the writer is quite unable to draw from them any such conclusion as he deduces. Following three different methods, after rupture of the medulla, in chloroform narcosis, and with no anaesthetic, the normal animals he examined are too few to serve as a guide, and his estimates of the leucocytes in the central vessels are so widely divergent that any conclusion as to whether increase or decrease is absolutely prohibited.

**Destination of the Leucocytes in Hypoleucocytosis.**—If, then, the leucocytes disappear, as it seems, from the circulating blood during hypoleucocytosis, one may rightly demand to know what becomes of them; nor is the proof of their disappearance complete until their destination has been established. The earliest clue to the fate of the leucocytes was furnished by Wyssokowitsch (16), when, in 1896, he found that injected bacteria rapidly disappeared from the blood, and were to be found by Gram's stain in the lumen of the capillaries and in the endothelial and fixed connective-tissue cells of the liver, spleen, and kidneys. In a further study of the same subject (17) he located the bacteria at the same points, but claimed that the leucocytes had taken no part in the process of transfer.

In 1892 Werigo (18), without regard to the question of the disappearance of leucocytes from the circulation in hypoleucocytosis, found that in the capillaries of the liver, spleen, and kidneys there was a large increase of leucocytes within a few minutes after intravenous injection of bacteria. These leucocytes, or phagocytes, were apparently in the act of transporting bacteria to the endothelial cells of the hepatic capillaries. In many cases the leucocytes were so abundant as to form miniate emboli in the capillaries. Similar appearances, less marked, were seen in the spleen and kidney. He also described the normal flat endothelial cells of the hepatic capillaries as much swollen, often partly occluding the lumen of the capillary, sending out protoplasmic processes to entangle the passing leucocytes. One or several leucocytes were sometimes seen completely engulfed by the endothelial cells, forming a lenticular giant cell, the nuclei of which were strung along the capillary wall.

With these data in mind, the microscopic examination was made of the organs of the rabbits used in the preceding experiments. The tissues, having been hardened as described, were embedded in celloidin, and sections were cut of a uniform thickness of one two-hundredth of a millimetre, and stained with hematoxylin and cosin by Gram's method, and by Loeffler's methyl blue. As a control, the organs of normal rabbits were first examined. In the normal livers the writer found the capillaries to present all the appearances Werigo describes after the injection of bacteria, except thrombi in the vessels and bacteria in the cells. Many of the endothelial cells were quite flat, their bodies invisible, and their nuclei projecting characteristically into the lumen of the capillary. Many others, however, were much thicker, occupying a large part of the capillary lumen, containing often pigment granules, apparently sending processes out into the capillaries. All stages of the so-called "giant cells" were seen, from a single well-defined leucocyte adherent to an endothelial cell to a long protoplasmic mass containing a half dozen nuclei. These appearances were too uniform and distinct to be regarded as artifacts, and were seen in every one of nine apparently normal cases examined.

On comparing sections of normal livers with those of the animals killed after injection of bacteria, it was not easy to convince one's self that there was any increase in the number of leucocytes in the capillaries. Only once was such an increase unmistakable, when numerous small thrombi were found, each containing twenty to a hundred polynuclear leucocytes. But such thrombi, having occurred once in twenty cases examined, might reasonably be rejected as evidence of an invariable increase of leucocytes.

The swelling of the endothelial cells seemed rather more marked and more frequent than in the normal livers, but even after two hours many endothelial cells remained quite flat and seemed entirely unaffected by the influences which had caused such great changes in their immediate neighbors. Such features gradually became so striking as to suggest some real difference in character between the swollen and the flat cells. A thorough search over sections of the liver and other organs, stained by Gram's method or by Loeffler's methyl blue, very seldom revealed
any bacteria within the leucocytes or endothelial cells. This negative result may be partly explained by the comparatively small quantity of the culture injected. No evidence was found of either mitotic or amitotic division of leucocytes.

A comparison of the general appearance of the liver tissue before and after injection failing to give satisfactory evidence of a uniform increase of leucocytes, it was decided to make a count of their numbers in the cubic millimetre of hardened tissue. For this purpose a mechanical stage and a Zeiss one-twelfth immersion lens were used, and the leucocytes in one square millimetre of each section were counted. The sections being one two-hundredth millimetre in thickness, the result of the count was multiplied by two hundred, which gave the number of leucocytes in one cubic millimetre of tissue. An attempt was made to count the leucocytes in the small arteries and veins before and after injections, but the results were so nearly equal in the two cases that no conclusions were possible.

An examination of the subjoined tables will show that, according to this method of estimate, there was a steady increase of leucocytes in the hepatic capillaries for at least two hours after the injection of Bacillus pyocyaneus into the ear vein. During the same period a marked diminution of leucocytes had been demonstrated in the circulating blood. In four instances two cubic centimetres of the sediment from a three-days-old broth culture of Bacillus anthracis was injected, instead of the smaller quantity of Bacillus pyocyaneus.

The examination of the lungs was made in the majority of cases without previous inflation, as it seemed probable that such treatment would disturb the condition of the capillaries. From a general survey of sections from the lungs prepared in this way, it appeared probable that the pulmonary capillaries contained many more leucocytes after the injections, but any attempt at a numerical comparison was quite impossible. The lungs in the remaining cases were therefore slowly distended with forty-per-cent. alcohol to rather less than their normal size in expiration, and from sections of the organs thus prepared the number of leucocytes in the cubic millimetre was computed as described for the liver. The separation of the nuclei of leucocytes from those of other cells in the pulmonary parenchyma was often difficult and sometimes impossible, but the total error from this source is believed not to seriously affect the comparisons. The injections of Bacillus anthracis affected the lungs more powerfully than did Bacillus pyocyaneus, the former producing many minute thrombi in the distended capillaries. In the capillary endothelium no changes could be discerned such as were constantly found in the liver.

In the kidney no changes could be discovered in the endothelial or fixed connective-tissue cells, capillary vessels, Malpighian tufts, or larger arteries or veins. The multinuclear leucocytes were counted in twenty Malpighian tufts in each of five normal kidneys and in five cases after injections. Only multinuclear leucocytes were here counted, because of a difficulty experienced in distinguishing the nuclei of lymphocytes from the short spherical nuclei of the endothelial cells.

In the marrow of the femur the leucocytes in the capillaries were often slightly increased in numbers, and rather
more of the large unimolecular elements of the marrow appeared to be free in the circulation, but the extent and constancy of these changes were not very manifest. The examination of the spleen did not give convincing evidence either for or against an increase of leucocytes, although pulp cells, endothelial cells, and sections of blood in vessels were carefully compared. The anemic condition of the spleen found after the injection of bacteria must stand as strong presumptive evidence against any immediate increase of leucocytes in this organ.

Leucocytolysis.—There remains the question of an actual destruction of leucocytes in the circulating blood by bacterial products, and of its importance in accounting for the disappearance of these cells in hypoleucocytosis. Most investigators have failed to find in the blood definite traces of the solution of leucocytes. The weight of opinion is against the belief that the blood plates are products of the disintegration of multinuclear leucocytes. It is possible, however, that among the multitude of irregularly defined granules constantly met with in the routine of blood examinations some may be products of the disintegration of leucocytes. Among the authorities who maintain that actual destruction of leucocytes is a factor in their disappearance in hypoleucocytosis may be mentioned Lowit, Roemer, S. S. Botkin, Holtzmann, E. Botkin, et al. (19). That no such destruction occurs in the blood is more or less strictly held by Schulz, Rieder, Werigo, Medweideff, Goldscheider and Jacob (19). Since the publication of E. Botkin’s (19) experiments on the solubility of leucocytes in peptone there remains little doubt that injection of bacterial products directly into the circulation may destroy a considerable number of leucocytes.

Botkin treated pus with solutions of peptone, and was able to follow, under the microscope, the changes that occurred in the leucocytes. Within fifteen minutes after treatment with peptone the granules began to disappear from the protoplasm of the leucocytes; they became translucent, finally invisible, while the nuclei lost their color and gradually fell in pieces. In twenty-four hours eighty per cent. of the leucocytes in the mixture had disappeared.

Throughout the present work, after the injections, granular particles were constantly found in the blood, which might equally well have been regarded as deformed blood plates, or as fragments of the nuclei of leucocytes. These granules were more abundant if the blood was allowed to stand in the mixer for an hour. In such specimens fragmentation and complete solution of the protoplasm of leucocytes could be plainly followed, while the nuclei, more difficult of solution, were seen to break up into irregular, faintly stained granules. At the end of two hours a diminution in the number of leucocytes was regularly noted. After four hours this diminution became marked, and in some specimens, examined eighteen hours after drawing, it was impossible to find a single leucocyte among the clumps of developing bacilli.

No such changes occurred in the blood drawn from healthy rabbits before injection.

If the injections of one cubic centimetre of a broth culture of Bacillus pyocyaneus can in one hour so affect the blood that the solution of leucocytes can be discerned in the counting chamber, it is probable that the larger injections used by most experimenters have furthered the impoverishment of the blood by direct leucocytolysis. It seems probable also, from analogy, that the bacterial products thrown into the circulation at the onset of an acute disease like pneumonia must destroy a moderate number of leucocytes. But, since nearly complete disappearance of leucocytes from the blood can be produced by large injections within a few minutes, one must at present be content to regard leucocytolysis as only an accident in the course of hypoleucocytosis.

Summary.—1. Within eight minutes after rupture of the medulla in rabbits very little change occurs in the number of leucocytes in the blood of the central vessels.

2. Either narcosis in rabbits has very little effect on the location of leucocytes in the circulating blood.

3. The view of Rieder and Schulz, that no change in the sum total of leucocytes in the blood ever occurs in leucocytosis, is incorrect, and may be disproved by examination of rabbits’ blood in the stage of hypoleucocytosis, either after rupture of the medulla or, more conclusively, in ether narcosis.

4. After intravenous injection of certain bacteria and their products, the majority of the leucocytes, especially the multinuclear forms, disappear uniformly from all parts of the arterial and venous circulation.

5. The leucocytes that disappear after bacterial injections are to be found, more or less stationary, in the capillary vessels, especially in the lungs and liver.

6. The appearance of the endothelial cells of the hepatic capillaries indicates that these cells may take more than a passive part in detaining the leucocytes within that organ.

7. Leucocytolysis is apparently a secondary and essential factor in the production of hypoleucocytosis.

8. It remains an open question whether hypoleucocytosis depends upon a simple mechanical sifting of swollen and cohesive leucocytes by the capillary endothelium or upon a determination of these leucocytes, by chemotactic influence, to specialized capillary endothelium in the viscera.

9. The appearance of the hepatic capillary endothelial cells, both before and after the injection of bacteria, points to a possible function of the liver as the physiological scavenger of the body, and, in pathological conditions, as a special organ of phagocytosis.

Addendum.—While the results of the present work were being prepared for publication, the extensive and valuable study of Goldscheider and Jacob (20) came under observation. Their experiments were specially suggested by the theories of Lowit and Schulz.

By injecting minute doses of a glycerin extract of the spleen they succeeded in producing marked increase in leucocytes without appreciable previous decrease.

They call attention to the remarkable variations in the numbers of leucocytes found by Schulz in the central veins, and discredit all his results because the specimens of blood were drawn after rupture of the medulla or other vitiating procedures. In two experiments they find the leucocytes diminish greatly in the ear vein immediately after rupture.
of the medulla, and infer, but do not attempt to prove, that there is a corresponding and simultaneous change in the central vessels. After convincing themselves that ether narcosis has no effect on the location of leucocytes, they examine the blood of three normal etherized rabbits in the stage of hypolecocytosis and one in hyperleucocytosis, and thus attempt to combat the more numerous experiments of Schulz.

If Goldscheider and Jacob had proved that rupture of the medulla caused as pronounced and immediate a change in the central veins as it does in the ear vein, they might justly discredit Schulz’s results. But the writer’s experiments show that, if the operation is done within four to eight minutes, and before the blood pressure is markedly reduced, blood may be drawn from the central vessels before any appreciable change occurs in the number of leucocytes. Many of Schulz’s specimens were taken within this time, and some of his operations were performed under chloroform. As to the actual data presented, the weight of evidence must still remain with Schulz.

One of the most valuable features of Goldscheider and Jacob’s work is to be found in their report of the microscopic examination of the organs, by which they locate, principally in the pulmonary capillaries, the leucocytes that disappear after injections of bacteria. With one prominent exception, they failed to find in the liver the appearances described by Werigo, and conclude that this organ is little concerned in the phenomena of hypolecocytosis.

A Hitherto Unknown Symptom of Complete Facial Paralysis.—Goloschieder (Rev. gén. d’ophtalm., Jan. 31, 1894) considers that in all cases of complete facial paralysis, with paralysis of the palatal harens, there is never any lacrimation on the paralyzed side, and the eye is perfectly dry.

LEFT HEMIPLEGIA FOLLOWED BY LOSS OF THE DEEP AND SUPERFICIAL REFLEXES, CONSIDERABLE MUSCULAR ATROPHY, MARKED ANESTHESIA IN THE DISTAL PORTIONS OF THE LIMBS, LOSS OF PARASYMPATHETIC ACTIVITY, AND REACTION OF DEGENERATION OF THE MUSCLES ON THE PARALYZED SIDE.

By J. T. ESKRIDGE, M. D.,
DENVER, COLO.,
PROFESSOR OF NERVOUS AND MENTAL DISEASES AND MEDICAL JURISPRUDENCE IN THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF COLORADO; NEUROLOGIST TO THE ARAPAHOE COUNTY AND ST. LUKES’S HOSPITALS.

With Remarks by FREDERICK PETERTON, M. D.,
NEW YORK.

Report of the Case by Dr. Eskridge.

The trophic disturbances found in the case which is reported in this paper differ so widely from those that usually occur in old hemiplegias of brain origin, that a full record of all the symptoms is demanded.

Some years ago Eisenlohr cited two cases of cerebral palsy in which atrophy and degenerative reaction occurred, and recently he has had opportunity to make autopsies in both of his cases, finding degeneration of the peripheral nerves to account for the trophic changes in the affected muscles (F. Peterson, Journal of Nervous and Mental Diseases, April, 1894, p. 263). Dr. C. A. Herter states that “in one case coming under his observation a woman aged seventy years, the patient had a series of slight apoplectic attacks, succeeded in time by complete paralysis of the right side of the body, face, arm, and leg, and complete motor aphasia; at the end of a week distinct atrophy of the muscles of the forearm was noticeable, and at the end of a month was very pronounced. The faradic irritability of certain muscles of the forearm was very much reduced. The contractions were exceedingly sluggish, and the reaction of degeneration was undoubtedly present. The galvanic irritability of these muscles was somewhat diminished” (ibid., p. 257). The literature relating to muscular degeneration following cerebral palsy in the adult is exceedingly meager, but the cases that are on record have not been made public in journals to which I at present have access. To make this case the more interesting, I have asked my friend, Dr. Frederick Peterson, of New York, to add any comments that he may see fit, together with the literature of the subject.

The patient, a Swedish widow woman, forty-two years of age, domestic by occupation, came to Colorado directly from Sweden in 1886. The father died of heart disease. The mother died, aged forty-two years, but the cause of her death is unknown. Other portions of the family history are negative. With the exception of an attack of measles when a small child, the patient enjoyed excellent health until she suffered from small-pox nine years ago. She apparently made a complete recovery from the latter and remained well for two years. In 1888, after having been exposed to the sun’s rays, she suffered severely for some days from a headache and physical depression; but these symptoms soon passed off and she again felt as well as usual. In January, 1891, she had an attack of “the grip,” and on the morning of January 25th, after convalescence had fairly set in, she was sitting in a chair, when she experienced a peculiar numb sensation in the left side of the head, face, and throughout the left side of the body, including the arm and leg.
The feeling alarmed her, and she attempted to stand, but found that her left leg was paralyzed, and about the same time she noticed that the left arm and the left side of the face were paretic. She is sure that consciousness was not affected. Within a few hours after the first appearance of the paralysis she was able to walk with slight assistance. For the next two or three years there was no much change in her condition, with the exception that the paresis passed away in the face. About two months ago she experienced considerable pain in the left leg below the knee, with more or less pain in the left knee and ankle joints. Since then she does not think she has been able to walk as well as before. The same numb sensation that she experienced in the left arm and leg in January, 1891, when her disability from paralysis began, still persists. She presents no distinct evidence of syphilis, denies alcoholic indulgence, and says she has never been subject to headache. Her speech has not been affected by the brain lesion.

The patient was admitted to the Arapahoe County Hospital, May 29, 1894. Examination, May 29th. She is able to walk with the assistance of a cane, but locomotion is very difficult on account of extreme weakness of the left leg. She exhibits no ataxia in any position that she assumes, but she is unable to bear much weight on the left leg. The flexors and extensors of the left ankle are completely paralyzed, and the only movement that she can exert with the left foot is slight flexion of the great toe. The extensors of the left knee are too weak to extend the leg when she is sitting, and the flexors of this joint are extremely weak. The flexors of the left hip are absolutely powerless, and the extensors almost so. All movements of the right leg and foot are normal and vigorous. Dyn. R. 120; L. 60. Flexors and extensors of the left hand are weak, those of the elbow fairly strong, and the muscles of the left shoulder are but little weaker than those of the right. All the muscles of the right hand and arm are strong. There is little or no perceptible weakness of the muscles of the left side of the face. The tongue is protruded in the median line. Knee jerks: R., increased; L., absent. Ankle clonus absent. Reflex of the tendo Achillis: R., absent; L., absent. Plantar reflexes absent. Abdominal reflexes: R., present; L., absent. Reflexes of extensor muscles of forearms: R., increased; L., absent. Biceps: R., increased; L., lessened. Triceps about normal. Measurements in inches—Calf: R., 13; L., 12\frac{1}{2}. Just above knee: R., 16; L., 14\frac{1}{2}. Forearms: R., 10\frac{1}{2}; L., 10. Biceps: lax—R., 12; L., 11\frac{1}{2}; contracted—R., 13\frac{1}{2}; L., 12\frac{1}{2}. All the muscles of the left leg are soft and nearly flaccid.

Tactile Sense.—She is unable to recognize the contact of a feather on the left leg from the knee downward, including the foot and ankle. Over the left thigh this sense is present, but much less acute than it is on the right side. Over the palmar surface of the left hand and the dorsal surface of the fingers tactile sense is nearly lost. It is also much impaired from the elbow downward, but not nearly so greatly as it is in the left leg. Over the entire left side of the trunk there is lessening of the acuity of tactile sense, with delay in rapidity of conduction of tactile impressions, but in no portion of the trunk, around the anus, or over the external genitalia, are there any spots of tactile anesthesia. In the left arm from the elbow upward and over the left side of the neck, face, and head there is perceived a slight impairment of tactile sense; but this can only be recognized by comparing these areas with the corresponding ones on the opposite side. Tactile sense is normal on the right side. Temperature sense is perturbed most markedly where tactile sense is most disturbed. Both warm and cool substances give an impression of cold at first. After warm substances have been in contact with the skin for several seconds she then says that they feel warm. There is a slight persion with a delay of temperature sense throughout the left side of the body. Localization sense is nearly normal, but slightly perverted over the left foot and ankle. Pain sense is most perverted over the anesthetic areas, but on no portion of the body is it absent. Pressure and joint senses normal. It is impossible to test muscular sense in the affected parts on account of the extreme degree of paralysis. All sensory phenomena are normal on the right side. Eyes: R. V. = \frac{6}{6}; L. V. = \frac{6}{6}. Pupils equal and react to light and accommodation. Fields normal, except slight narrowing of the nasal side of the left eye. No weakening of the external ocular muscles. Fundi and discs nearly normal. There is no disturbance in taste, smell, and hearing. Muscular response to faradic current (the large size Fleming battery was used). Tibialis anticus: R., I plus 2; L. will not respond to the strongest current. Peroneus group: R., I plus 2; L., no response to strongest current. Extensor longus digitorum: R., II; L., no reaction to strongest current. Posterior tibial group: R., I plus 4; L., III. Rectus femoris: R., I plus 2; L., no response to strongest current. Posterior thigh group: R., II plus 1; L., IV plus 1\frac{1}{2}. Flexors of wrist: R., I; L., I plus 2. Extensors of wrist: R., I plus 2; L., I plus 4. Triceps: R., I plus 3; L., I plus 2. Biceps: R., 1; L., I. Deltoïd: R., I plus 3; L., I plus 3. Reactions to the galvanic current—Tibialis anticus: K Cl C, R., 5 mil.; L., 30 mil., no response. An O C, 6\frac{1}{2} mil.; L., 30 mil., no response. Peroneus group: K Cl C, R., 4 mil.; L., 25 mil. An O C, R., 5 mil.; L., 20 mil. Extensor longus digitorum: K Cl C, R., 6 mil.; L., 30 mil., no response. An O C, R., 7 mil.; L., 30 mil., no response. Posterior tibial group: K Cl C, R., 6 mil.; L., 15 mil. An O C, R., 7 mil.; L., 12 mil. Rectus femoris: K Cl C, R., 8 mil.; L., 30 mil., no response. An O C, R., 10 mil.; L., 30 mil., no response. Extensors of wrist: K Cl C, R., 4 mil.; L., 6 mil. An O C, R., 6 mil.; L., 7 mil. Flexors of wrist: K Cl C, R., 2\frac{1}{2} mil.; L., 5 mil. An O C, R., 5 mil.; L., 6 mil. T estimated movements of the tibia and fibula: K Cl C, R., 4 mil.; L., 4\frac{1}{2} mil. An O C, R., 6 mil.; L., 6 mil. Biceps: K Cl C, R., 4 mil.; L., 4\frac{1}{2} mil. An O C, R., 6 mil.; L., 6 mil. Deltoïd: K Cl C, R., 5 mil.; L., 5 mil. An O C, R., 6\frac{1}{2} mil.; L., 6 mil.

The cause of the hemiplegia in this case is probably thrombotic occlusion of the arteries supplying the right internal capsule, and the muscular atrophy with the electrical changes and loss of myotatic irritability have been the result of unilateral multiple neuritis. The case would possess greater interest if it had been under intelligent observation from the onset of the hemiplegic symptoms until the present. In the absence of a complete history it must be uncertain whether the neuritis dates from the time near the occurrence of the cerebral paralysis or from March, 1894—a little more than three years subsequently, when she experienced considerable pain in the left leg below the knee with more or less pain in the left knee and ankle joints. She does not think she has been able to walk as well since March, 1894, as she was previously, and she does not know when the wasting of the left leg and arm began.

Remarks of Dr. Peterson.

In the great majority of cases of hemiplegia there is no atrophy of muscles on the affected side. Sometimes we note a slight diminution in the size of the limbs involved, but this is merely from inactivity and disuse. It is not a true trophic change.

In certain rare cases, however, the diminution in size is
so marked as to merit the name of an actual atrophy. These cases, one of which is described above by Dr. Eskridge, are so rare that, out of many hundreds of hemiplegics observed by me, I can recall but three or four in which the paralysis was accompanied by amyotrophy. Darkschewitsch (1) found six out of fifty-nine cases of hemiplegia examined for this purpose presenting muscular atrophies.

The behavior of the muscles in electrical examination is of considerable interest, because reaction of degeneration has always been one of our most trusted means for differentiating the two kinds of paralysis due to lesions in the cortico-spinal and spino-muscular portions of the motor tract. Now, in some of these cerebral amyotrophies there is a change in the electrical reactions, but this change must be looked upon as exceedingly rare even in these cases. As a rule, we shall find perfectly normal reactions as regards quantity and quality, whether to faradism or galvanism, in these cases of cerebral amyotrophy. The muscular atrophies from cerebral lesions behave in this respect very much like atrophies from joint lesions, the so-called arthropathic amyotrophies. But in a certain small minority of cases we may find some electrical changes, usually quantitative, very seldom qualitative.

As long ago as 1887 Wernicke (2) called attention to the diminution of faradic and galvanic irritability on the paralyzed side in hemiplegia with hemianesthesia. Even before that, Erb, in his book on electricity, had noted the occasional occurrence of diminished excitability in hemiplegic cases. Quincke (3) found very slight diminution of electrical irritability in his cases. In the six cases of Darkschewitsch the electric reactions were normal in four, and there was merely a quantitative reduction to faradism and galvanism in the other two cases. Eisenlohr (4) reported both quantitative and qualitative changes—in fact, complete reaction of degeneration—in his first case.

It is therefore proper to conclude that a reaction of degeneration in a case of cerebral amyotrophy is an extremely rare phenomenon.

What is perhaps of greater interest and importance in such cases is the origin of the atrophy. This is still a mystery, and one well worth solving. Various theories have been advanced to explain it, such as the following:

1. That there are trophic centers in the motor cortical area (Quincke).
2. That there are changes in the ganglion cells of the anterior horns (Charcot, Leyden, Brissaud (5), Joffroy, and Achard).
3. That the atrophy is due to peripheral neuritis (Déjérine, Eskridge).
4. That the wasting is explicable on the ground of deficient nutrition due to purely vaso-motor changes and diminished circulation (Roth and Muratow).
5. That there are functional disturbances in the spinal trophic centers due to dynamic influences from the lesion above.
6. That there are functional disturbances in the spinal trophic centers due to dynamic influences of a reflex kind from below along sensory paths.

Now, as to the results of autopsies in such cases, there are but few good data at hand.

As to the cerebral lesions in such cases, they vary in site, but are mostly about the internal capsule and optic thalamus.

There is usually descending degeneration of the pyramidal tract involved.

The ganglion cells of the anterior horns were found normal in one case by Quincke, in two by Eisenlohr, in one by Steiner (6), and in one by Darkschewitsch. The ganglion cells of the anterior horns were affected in two cases reported by Joffroy and Achard (7).

The anterior roots were examined by Darkschewitsch and Steiner in their cases and were normal.

The peripheral nerves were normal in all the cases where they were examined. Positive statements to this effect are made by Darkschewitsch and Steiner. Eisenlohr found slight simple degeneration in some of the peripheral nerves. This should not be called a neuritis.

The muscles themselves, examined by Darkschewitsch, presented a simple, not a degenerative, atrophy.

Thus we may say that in four of the six autopsies here described there were none of the anatomical changes in the spino-muscular portion of the motor tract usually incident to amyotrophy. This is corroborated by four careful observers. The joint research of Joffroy and Achard, in which they describe changes in the anterior horns, stands alone in this respect.

It is worth while to consider, in connection with the cerebral amyotrophies of adults, the enormous retardation in growth of the affected extremities in infantile cerebral palsies. The paralyzed members grow, of course, as the child waxes in years, but the striking difference between the two sides can be explained only in one of two or three ways: Either there are trophic centers in the brain affected by the lesion, or the cerebral disorder influences dynamically the trophic centers in the spinal cord, or the retardation in growth may be due to vaso-motor disturbances and insufficient blood-supply on the side involved.

A peculiar feature, too, of the cerebral amyotrophies of adults to which Darkschewitsch has called attention is the occurrence of actual arthropathies in many cases of hemiplegia, and the coincident muscular atrophies in some of such cases may be considered as joint atrophies after all. It will be noted that the case recorded by Dr. Eskridge presented evidences of arthropathic conditions in the knee and ankle joints of the paralyzed side.

Altogether, then, we may infer that there are as yet no conclusive data upon which to found a tenable theory as to the origin of muscular atrophy in hemiplegia.

A clinical fact worth remembering is that, as a rule, the amyotrophy comes on very rapidly and early after the onset of the hemiplegia, being sometimes noteworthy within two days.

Literature.

INSOMNIA IN SURGERY, AND ITS TREATMENT.

By GEORGE G. VAN SCHAICK, M.D., ATTENDING SURGEON TO THE FRENCH HOSPITAL AND TO ST. VINCENT DE PAUL ORPHAN ASYLUM.

In the practice of general surgery we are constantly called upon to relieve insomnia due to a variety of causes that may be roughly classified as follows:

1. Nervousness due to fear of operation.
2. Depreciated nervous conditions due to exhausting diseases and to pain.
3. Post-operative nervous influences.
4. The influence of certain special surgical diseases.
5. Complicating pathological nervous disorders.

It was easy enough to extend this list or to alter it in many ways, yet it will serve our purpose, since practically all forms of insomnia observed in the practice of surgery will be found to bear an antilogical relation to one or more of these causes.

It may at first sight appear trivial to insist upon the insomnia due to fear of operative interference. We have all observed it, nay, we all expect it in a certain proportion of our patients. But the question is whether we pay enough attention to it, and whether we realize that efforts made to relieve it are rewarded by better results.

The nervousness and fear experienced by many patients after learning that an operation is necessary is often a source of truly cruel suffering, to which men are, as a rule, quite as subject as women. The surgeon who merely tells his patient that an operation is imperative, that it is to be performed at a certain time, and who, after a few words of encouragement, departs without a thought about the nervous condition of the patient, often fails in what is his chief mission—the prevention of suffering.

If about to be operated upon within a day or two, the patient, if of a nervous and fretful disposition, will lie awake most of the night thinking about operations, pain, and death, evoking gruesome horrors from his sensitive mind, listening to the beating of his heart, suddenly become perfectly audible, and wishing at times for a speedy death to relieve at once the terrors that are so greatly magnified in the stillness of the night.

In the morning, of course, his general condition is worse than on the previous day; he will take the anesthetic badly, and sometimes, after the operation, will suffer from shock in a manner entirely unexpected by the surgeon. Nor, is this picture an exaggerated one, as all surgeons of experience will testify.

Such a state of things is unnecessary, and hence inexcusable. The patient should have been made to sleep. Watch the effect of your decision upon him. If the pulse becomes more rapid, if the face flushes, if he looks frankly scared, or if he merely assumes a dogged appearance, looking fixedly upon one point, wrinkling his brow, clenching one or both fists, the probabilities are great that his sleep will have to be eked out with a hypnotic. Other patients will endeavor to conceal their fear and nervousness, yet this is commonly easy enough to detect. The intensity of these feelings is often shown by the statements so generally made after operations, that "it was not half so bad as I expected," that they "felt nothing at all."

Fear of operation in pre-anesthetic days has actually caused death. This fear is naturally no longer experienced in the degree observed a few generations ago, yet it is an important factor in some cases, and hence demands treatment.

Where pain is not the principal factor I know of no better hypnotic for this purpose than trional, to which I give the preference on account of its comparatively rapid action, of its lack of after-effects, and of the deep and restful sleep it induces. I am in the habit of ordering a fifteen-grain dose, to be repeated if necessary by another one within an hour. The patients awake refreshed, are apt to be more hopeful, and are in every respect better subjects for operation than those who have been allowed to spend the night in demoralizing wakefulness.

In cases of long-continued exhaustion and pain, as in supplicative and other diseases, the surgeon always attempts, if time allows, to improve the general condition of the patient before resorting to an operation. In such cases there often exists a severe degree of insomnia, and trional will often have the happiest effects. Chloral, while it is probably the most effective drug known for producing sleep, is a depressant of the heart, and must therefore be avoided in all chronic diseases which have caused general exhaustion. In some conditions constant pain is apt to lead one to think that nothing but morphine will serve to induce sleep. This is an error in many cases. Pain, long continued, becomes a habit to a certain extent, and many patients are able to eliminate it, as it were, from the causes that produce insomnia if their restlessness and nervousness can be quieted. The writer, while suffering intensely from a dissection wound, was readily made to sleep with thirty grains of trional, notwithstanding the throbbing pain left after deep incision of the pleurisy. Hence, while trional
has no direct influence upon the relief of pain, it will often prove useful in inducing sleep.

The third class of causes which I have mentioned—namely, post-operative nervous influences—is an important one. For the relief of pain after operation, morphine subcutaneously is undoubtedly frequently indicated, but there are many instances in which pain is not a very important factor in post-operative nervousness and agitation. There is at times a semi-hysterical condition, a restlessness and jactitation that are quite detrimental to the patient, and which occasionally would seem to represent a state of relaxation occurring in nerves that have been highly strung by fear, suffering, and the many other mental and bodily influences that the patient has been subjected to. This condition, occurring without serious evidence of shock, is often happily relieved by trional in moderate doses. Its use causes no depression of vitality, and, when given after the period of nausea has ceased, brings about a pleasant sleep that is highly beneficial to the patient.

The influence of certain special surgical conditions is one that is well recognized. It is probably best marked in the genito-urinary diseases of men. The insomnia, restlessness, and jactitation so frequently observed after urethrotomies, whether internal or external, are often decidedly amenable to the influence of the milder hypnotics, among which I give trional the preference. I have administered this drug in at least three cases of external urethrotomy, and in a number of internal urethrotomies. It should be remembered that there is no operative procedure upon the urethra, however mild, including the mere passage of metallic sounds, that may not, in some individuals, be followed by severe nervous manifestations. And these manifestations are frequently quite independent of so-called urethral fever. In the case of a comparatively trivial urethral operation it matters not very much whether the patient has one sleepless night, as far as the ultimate result is concerned, but he will be very apt to have a good opinion of a surgeon who gives him a good night's sleep. In the more serious operations upon the urethra or the bladder I commonly operate in the morning, giving half an hour before the anesthesia a hypodermic of morphine. This keeps the patient comparatively free from pain during the day, at the close of which I order twenty to thirty grains of trional. The probabilities are strong that the patient will sleep reasonably well, and that thereafter morphine will no longer be needed. If, on the other hand—and this is true of every operation—we give morphine after a procedure involving any degree, however slight, of after-pain, the patient will be sure to insist upon it on succeeding nights.

This nervous condition is often present after operations for piles, and may at times be seen as severely marked after the mere snipping off of a small hemorrhoid as after a Whitehead operation.

Abdominal sections, in which thirst is so apt to complicate the other nervous disturbances, are also very frequently followed by insomnia of a more or less severe type. In two instances trional by the rectum has, in my hands, proved quite successful. The stomach is so weak, and we are so anxious to avoid vomiting in such cases, that the rectal method of administration is by far the best.

The insomnia caused by pain and muscular contractions, together with unwonted immobilization in the treatment of fractures, is very amenable to the good effects of trional. Here I may mention the case of a sailor admitted to the French Hospital on November 29, 1894. He had fallen astride an iron stanchion during a storm at sea. There was a fracture of the right thigh, partial rupture of the urethra, infiltration of urine, and a large hematoma of the right ischio-rectal region. Under anesthesia the blood clots were turned out, the urethra catheterized, and the fracture dressed. A full dose of trional procured a good night's sleep, and the patient is now doing very well.

In cancers and bone diseases the patients frequently get into a condition of chronic insomnia, which, in my hands, has in a number of cases been greatly relieved by trional.

The pathological nervous conditions which complicate surgical disorders and are apt to cause insomnia are of frequent occurrence. Alcoholism, generally to the degree of delirium tremens, and hysteria, seen in many forms, and whose influence is so marked in so-called hysterical joints, causing marked degrees of hyperesthesia, are both very common. Insomnia may be due to arterio-sclerosis in the class of cases in which intracranial headaches are frequent. It may also be due to insanity, to tubers and other diseases of the cord, and to the abuse of narcotics. In all such cases, when an operation is needed for some complicating condition, some hypnotic is absolutely necessary. We have the testimony of Dr. Russell Bellamy (New York Medical Journal, July 21, 1894) as to the good effects of trional in delirium tremens. It has not been my fortune to have recently met with any such cases, but I may be allowed to report one instance, of which I propose to publish a more detailed account, in which alcoholism was a prominent factor. Mrs. L. D., aged thirty-five years, was placed under my care through the courtesy of Dr. J. M. Ferrer, of the attending staff of the French Hospital, for trephining and removal of a large portion of the frontal bone, necessitated by a depressed fracture of the frontal of six years' standing, complicated by extensive necrosis. The patient was an opium-eater, and was also addicted to the use of alcohol in large quantities. The operation, though quite extensive and prolonged, was well borne by the patient, who, however, in a few days became nearly maniacal, insulting the attendants and nurses and being somewhat garrulous. Morphine had to be given for a few days, but was soon replaced by trional. The operation succeeded very well in relieving an intense headache localized over the forehead. In her case the trional appears to have replaced the morphine quite satisfactorily, the opium habit seems to have disappeared, and the patient, who prior to the operation had spent her time either in a state of opium narcosis or in howling with pain and excitement, is now a very quiet and comfortable woman. Her mode of life and her inability to obtain proper treatment at home or in an institution, owing to poverty, lead me to believe that she will soon resume the morphine habit.
I may therefore briefly conclude by stating:
1. That insomnia, from whatever cause, is an important complication of surgical disorders.
2. Its relief is necessary to the comfort of the patients, improves the prognosis and materially assists recovery after operations.
3. Where pain is the chief factor, morphine is the only drug that will relieve with certainty.
4. There are many surgical disorders in which insomnia may be relieved by trional; and, finally—
5. Trional is an excellent drug for the purpose, as it acts rapidly and safely, has no inhibitory action upon the secretions, seems to possess a stimulating effect, is well borne by the stomach, is easily absorbed by the rectum, and fails to produce unpleasant after-effects.

SOME SUGGESTIONS
IN BACTERIOLOGICAL TECHNIQUE.

By A. P. OHLMACHER, M.D.,
CLEVELAND, OHIO.

The following subjects are here considered:
I. A simplified method of making a bacteriological autopsy on small animals.
II. The use of methyl violet in staining the diphtheria bacillus.
III. A note on methylene blue.

I.

The object of these modifications in the technique of bacteriological autopsies on the small animals used in experimental laboratory work is to do away with certain troublesome features of the ordinary methods. As practiced by the usual methods, a properly conducted bacteriological autopsy is a tedious task, especially in those cases in which pieces of the solid organs are required as material for culture experiments. It is necessary to have at hand several sets of sterilized cutting instruments—a set for each particular organ—or the instruments of a single set must be heated to a damaging degree in the free flame before and after the removal of each piece of tissue.

The novel feature of the modified method here proposed lies in the use of ordinary commercial benzene as the disinfecting agent, both in solution and in ignition. The benzene is employed as a bath for the instruments used in the autopsy, and also to disinfect the surface of the animal's body before the final incision. Benzene was chosen as the agent for these purposes because of its cheapness, its active disinfecting power, and its property of burning off of the surface of metallic or other substances without creating a great amount of heat. The details of an autopsy performed with the aid of benzene are as follows:

Two small artery catch forceps (Péan's forceps), a medium-sized dissecting forceps, and a pair of medium straight dissecting scissors are placed in a suitable beaker glass two thirds full of benzene. An extra dish of benzene and a medicine-dropper are also provided.

The animal (mouse, rat, guinea-pig, rabbit, etc.) is secured on its back to the dissecting board by tacks driven through the extended fore and hind legs. The skin of the ventral surface is incised in the median line from the symphysis pubis well on to the neck; lateral cuts are made on both right and left sides at the cephalic and caudal extremities of the median incision. The flaps of skin are carefully dissected from the underlying tissue throughout the entire length of the primary incision so as to thoroughly expose the subcutaneous tissues of the thorax and abdomen; then the flaps are secured with tacks so as to be well stretched out on each side of the body. This primary dissection is done with a coarse dissecting forceps and a pair of straight scissors, no particular efforts being made to avoid contamination of the exposed surfaces. Care must be taken, however, in this dissection that only the skin is removed, and that the abdominal and thoracic walls are not penetrated. With the medicine-dropper benzene is now applied to the exposed ventral wall of the body. The benzene is then ignited and allowed to burn until the flames spontaneously subside. Should any particular area not appear properly singed, the benzene may be again applied to this spot and set afire. Some care must be taken to keep the benzene from running over the flaps and into the hair of the animal, for here the fire does not subside so harmlessly as on the exposed moist surfaces. The dissecting scissors and forceps are now removed from the dish of benzene, and the benzene clinging to them is ignited and allowed to burn off. A fold of the abdominal wall in the median line is raised with the forceps and cut through with the scissors so as to avoid the underlying organs. As soon as a moderate cut has been made the edges of the incision are grasped with the artery forceps which have been flamed on their removal from the benzene; then the incision is continued down to the pubes and up through the thoracic cavity in the middle line, while the abdominal walls are held well up with the artery forceps. The artery forceps are now changed so as to grasp the edges of the deep cut at the diaphragmatic border, while the diaphragm is cut on each side so as to allow the incised ventral walls to be held well apart, exposing freely the thoracic and abdominal contents. If an assistant is available, the artery forceps can be intrusted to him; but in the absence of an assistant the operator can secure a comfortable exposure of the abdominal and thoracic organs by making lateral incisions at the ends of the deep incision, when the weight of the artery forceps will usually be sufficient to hold the walls well apart. The scissors and forceps are now wiped free of blood and tissue, replaced in the benzene, then removed and the adhering benzene ignited, and the removal of pieces of the organs desired for bacteriological study is begun. Of course, it will be necessary to sterilize the forceps and scissors as each particular organ is dealt with so as not to carry infectious material from one organ to another. All that is necessary for sterilization is to wipe the instruments, plunge them a moment in benzene, and burn off the benzene. It will also be necessary, especially in early autopsies, to avoid contamination of the remaining organs from the blood which flows from those already cut. This can be avoided by following a proper order in attack.
ing the various organs, depending, of course, on the object of the examination.

From a considerable practical experience with this method, the author is ready to conclude that it is simpler, more cleanly, more expeditious, and more saving of instruments than the usual methods of bacteriological autopsy. The proportion of accidental contaminations after this method is certainly smaller than I have ever observed with any other procedure, and this occasional contamination is doubtless due to air infection and not to imperfect sterilization of instruments and body surfaces. Control experiments with culture media, made after benzene sterilization of scissors andforceps, show the method to be a safe one. Perhaps this contains a suggestion for surgeons, especially in emergencies when ordinary sterilizing appliances are not on hand.

II.

A very powerful and brilliant stain for the diphtheria bacillus, and one which strikingly shows the irregularities of the "typical" form, may be obtained by the use of methyl violet. The aniline which I have employed was obtained from Grübler, and is specified by him as methyl violet, 5 B. It is important to obtain this particular brand.

To make the staining solution a saturated alcoholic solution of the dye is added to water in the proportions of about one to ten. The exact proportion is not a matter of great moment, and a little experimenting will settle this question, and enable any one to make the staining solution at a moment's notice. This mixture keeps remarkably well.

The technique of staining with this solution differs in no essential feature from the common method practiced by bacteriologists. A fixed cover-glass preparation from the diphtheria culture is stained, with heat, for half a minute, then washed with water, dried, and mounted. Or the stain may be employed without heating by allowing it to remain in contact with the film of the cover-glass preparation for one minute, though the results are not quite so good as in the heated specimens. In any case the resulting preparations are stained with a brilliancy and beauty that quite surpass the more commonly employed stains, like Loëllier's methylene blue.

III.

For some time I have had considerable trouble in making a methylene-blue solution which would stain bacteria in a satisfactory manner. The stain was always too faint and imperfect to be satisfactory. This was true of the aqueous solution, Loëllier's alkaline solution, Gabet's decolorizing solution, and carboxylic acid solution, of methylene blue. Finally, settling upon the aniline as the source of the trouble, I tried other brands, and discovered that an aniline which is recommended for another purpose was remarkably well suited to bacteria staining, while the dye recommended for bacteriological use was unsatisfactory. In these experiments I have confined myself to the use of Grübler's anilines. The unsatisfactory methylene blue is the brand which he recommends for bacteria staining (Methylen-Blau für Bacillenfärbung, Koch), while the blue which gave positive results is the one proposed by Ehrlich for blood work, especially for staining intra vitam (Methylen-Blau nach Ehrlich). The Ehrlich blue is considerably more expensive than the blue after Koch, but its solutions are much more powerful as staining agents, so that in the end it is an economy to use this brand when methylene blue is called for. As the same trouble has occurred in three different lots of aniline obtained from Grübler in original packages, I am sure the failure is not accidental.

CONGENITAL SPOTS ON ANNAMITES.

A MEANS OF RACIAL IDENTIFICATION: AND REMARKS ON LINGUISTICS IN CONNECTION WITH MIGRATION OF PEOPLES.*

By FRANKLIN B. STEPHENSON, M. D., A. A. S.,
SURGEON, U. S. NAVY; MEMBER OF THE ASIATIC SOCIETY OF JAPAN.

During a cruise on the Asiatic station, 1891-94, as surgeon of the United States ship Marion, it was the writer's fortune to visit Saigon, the French capital of Cochin China (or Indo-China). Near this city is the native town called Cholon, in which resides the Annamite savant Petras Truong Vinhky. He was educated in Paris, under the direction of the Jesuits, which accounts for the Latin word prefixed to his proper racial name. His house is a veritable museum of art and of letters, containing books and manuscripts in every language whose literature affords material for linguistic investigation. In addition to the classic philological studies of western thought—so-called Aryan—with which he is familiar, he has given special attention to the tongues and dialects of eastern Asia, from Sanskrit to Kanaka. Chief among these is Chinese, whose influence is felt by neighboring peoples in every direction. This influence he has been able to appreciate because of the similarity and analogy between modes of thought and language-forms existing in the Annamese and in the speech of the great nation of Confucius and Mencius.

At the time of this visit Mr. Vinhky gave the writer some of his works on the language and literature of his native land. These books, written in French, have been presented in his name to the Boston Public Library. The great desire of this scholar is to publish a comparative treatise on language, such as has not yet been given to the world, and for which he has accumulated much material.

Moreover, Mr. Vinhky is interested in other forms of science, as what follows may show. It appears that some travelers have reported the existence of a peculiar spot on newborn children among the Annamese. Previous to the cruise referred to, E. H. Bradford, M. D., of Boston, asked the writer to make inquiries on this subject. The short time of our sojourn at Saigon prevented such investigation; and, in reply to a written request, the following letter has been received from this Annamite gentleman:

"Yours of August 28, 1894, to hand, and the questions put to me I shall answer in few words. Your desire is, I understand, to know the nature of this spot or mark; whether it ex-

HUGHES: THE PREDOMINANCE OF MIND OVER MATTER.

[NEW YORK: J. J. HARRISON, 1894.]

Chapter 6: The Predominance of Mind Over Matter

HUGHES found small but would see gathered continued that sometimes, do would see and while it inging well with life. It M. dren death They in the have 270 short my reply a this definition, my opinion is that this ‘spot’ exists. Dr. Snelz, of Tokio, told me that in Japan it existed in every case of infants; that he had made sections of the skin, and found that it consisted of a deposit of pigment. In his opinion it was not a birthmark in that it usually faded in a short time; sometimes, however, it continued until adult life. I see that Nansen describes the same thing in eastern Greenland. Now, if we could get at observations in regard to this fact, it might enable us to determine the course of wandering of the different stocks. In China possibly some of the Tartar races may have this peculiarity, while some of the others not. It will be difficult to get at accurate information, and of course young children are not usually seen by strangers. I am extremely obliged for the note, and return the letter of your Annamite friend, which I read with much interest.

Whether or not this “spot” be a birthmark may, perhaps, remain undecided. However, in Foster’s Encyclopedic Medical Dictionary we find under the heading Nervus this definition: “Mother’s mark, birthmark, fancy mark, a congenital mark or growth in the skin due to an excessive circumscribed development, either of pigment, hair, or fibrous tissue, or of blood-vessels, the latter forming a vascular tumor composed of a collection of capillaries freely intercommunicating. . . . There is a great variety of neri. . . . Some continue to grow after birth.” As is well known, their color may be reddish or bluish, according as arterial or venous blood is more abundant.

The rest of Mr. Vinkly’s letter, referring to his linguistic labors, is both instructive and suggestive. He says:

“Let me add that I am still continuing my publications, but with difficulty, owing to my small resources. My Cours de langue annamite is now being published; and after, the other languages peculiar to Indo-China. L’administration is undertaking the expense of my French-Aannamite Dictionary, owing to my penury circumstances. Now, in order to finish my still numerous publications I would be glad if your country could give me a scientific donation, for which I would give the dedication of my work; and would also, in the measure of my resources, reply to the generosity of my donor or giver. I learn that in your country there are fortunes colossal, and the little unneeded excess which many possess, would render me a great service on the aim which I seek to accomplish; and further, their name would live lasting with my writings and my posterity. You might forgive my digression in opportune, but which is to me of good occasion; therefore I profit by it. However, trusting you will excuse me, and accept the warmest expression of my most sincere sentiments.

P. Theong Vinkly.

The linguistic problems with which Mr. Vinkly is engaged are also significant of the course taken by various peoples in their world-wanderings. By such means are traced the origins of the Hawaiian and Fijian natives, thus related to former inhabitants of Farther India and the regions to the westward. Investigations of both corporal and of psychical manifestations tend to the answering of the query suggested by Dr. Bradford.

AN ILLUSTRATION OF THE PREDOMINANCE OF MIND OVER MATTER.

BY M. E. HUGHES, M.D.,
BROOKLYN.

In calling the attention of the members of the medical profession to the following case, I do not do so with the intention of submitting for their criticism a “new treatment for the morphine habit,” and recommending the same for their consideration and adoption. This is not my intention. I merely desire to present for their perusal a series of facts illustrative of the supremacy of the mind in many important and very trying crises; which facts will, I think, prove both interesting and instructive to all medical men.

Early in December, 1894, I was summoned by telegram to the bedside of a young friend practicing medicine in a small town in western New York.

On my arrival, December 10th, I found him looking pale and wan, drenched with perspiration, and apparently suffering greatly from some cause.

He was extremely weak, and not inclined to talk; but, from his infrequent utterances, I gathered the fact that for four days he had battled with an attack of fifth-nerve neuralgia; and, though he had used in succession all the remedies he had ever heard suggested in the treatment of the same, he experienced no relief whatever.

A few hours later he confessed that he had contracted the morphine habit. Beginning in the latter part of September, 1894, with the injection of a fourth of a grain every morning, the dose had been rapidly increased in quantity and in the frequency of its administration, so that during the last month he had taken from three to four grains per diem.

For a few weeks a small dose had stimulated and brightened to a remarkable degree a temperament subject to frequent and often lengthy periods of profound melancholy; but soon a second dose was taken to overcome the depressing reaction which in a few weeks inevitably followed each injection, and in a short time he found himself indulging in large doses three times a day.

When the neuralgic attack began he had found that the combined effects of the usual remedies and the morphine had given him but little relief; in fact, he doubled the dose of morphine, but without the desired result.

The knowledge that such tremendous doses produced such trivial effects worried him greatly, and, however inopportune
the moment, he now determined to discontinue the use of mor- 
phine with as little delay as possible.
Realizing that he would probably need some assistance, and 
knowing that I had enjoyed exceptional (for one young in the 
practice of medicine) advantages in the study of such cases, 
and, above all, remembering the staunch friendship existing 
between us, he asked me to remain with him for a few days, 
or until the result of his experiment should become obvi- 
ously favorable, however, that I should allow him to adopt that 
course in regard to treatment which he chose, unless his condition 
should become such as to render this course unwise. To 
this I could not but consent.

Needless to say, I watched the progress of the case with 
great interest, and, as I desired to know exactly what medicines 
he would take, and in what doses, he readily consented to let 
my syrups and all the drugs in his possession.

I had another bed placed in his room, became in fact his 
nurse, so that my information might be exact in every respect.

December 16th.—During the day he had taken only two 
quarters doses of morphine, so that on my arrival at 
6 p.m. he must have been, and that he was, suffering 
terribly because of these greatly diminished doses, having taken 
five grains on December 9th.

About 10 p.m. he took another quarter-grain dose. During 
the night he slept an hour, but rolled and tossed about in a 
profuse perspiration, and in all human probability was suffer- 
ing the tortures of the damned.

11th.—Took three quarter-grain doses of morphine, three 
doses of a combination of strychnine sulphate and atropine 
sulphate, and four small doses of glucin.

All three were taken by hypodermic injection, as his stom- 
ach was exceedingly intolerant of medicine, and also, he 
stated, the preparation of the drug and the prick of the needle 
fooled his nervous system, as it were, leading it to believe that 
it was about to receive the aid of another dose of morphine in 
the performance of its functions, and thus gave him a little re-
lief temporarily. Then, too, the glucin stimulated him to some 
extent.

He slept but two hours during the night, his condition be-
ing about the same as on the previous night, and his suffering 
equally acute.

12th.—Treatment same as on the preceding day, except that 
the midday dose of morphine was reduced to an eighth of a grain.

During the day his neuralgic pains lessened considerably in 
severity, and the following day ceased to annoy him.

Slept very little at night, was very restless, and, as usual, 
drenched with perspiration.

13th.—Treatment as usual. Morning dose of morphine also 
reduced to an eighth of a grain. Vomited twice during the day.

At 10 p.m. took a quarter of a grain of morphine and 
stated that it acted as usual on a person not accustomed to it—i.e., 
delightful, soothing, and stimulating. For two hours 
he was apparently in excellent spirits, in marked contrast to 
his usual condition since my arrival, which was one of extreme 
irritability and quite evident suffering. He had no inclination 
for exercise, and remained in bed, with no desire to speak or 
to be spoken to. During the night he slept about five hours. 
Still perspired very freely.

14th.—Dropped the midday dose of morphine. Other 
treatment the same. He stated that each dose now acted as it 
normally should, and the quarter-grain dose at 10 p.m. was 
again followed by about five hours' sleep—i.e., he went to 
sleep about two hours after its administration and slept for 
five hours.

15th.—Treatment same as on previous day. Slept fairly 
well at night. Dropped the midday dose.

16th.—Dropped the morning dose of morphine. Continued 
to sleep from five to six hours every night.

17th.—Reclined on a couch the greater part of the day. He 
suffered much less than on the previous day; but his extreme 
irritability, so foreign to his temperament in health, was proof 
positive to me that he had not yet won the battle by any means.

At 10 p.m. reduced his dose to an eighth of a grain, and he 
slept quite well. He still continued to inject atropine, glucin, 
and strychnine; and it was not until ten days later that he dis-
continued the use of the two former, though he gradually 
minimized the frequency of their administration. The injections 
of strychnine were kept up for four weeks.

18th.—Took a twelfth of a grain of morphine at 10 p.m. 
From this date he was out of bed during the entire day. His 
appetite improved, and he stated that the "morphine pains" 
were far more easily borne, though he was greatly annoyed by 
profuse "sweats" recurring at frequent periods.

He is, I believe, occasionally troubled with these sweats up 
to the present time.

Throughout the entire period drenching sweats proved to be 
the most important objective symptom, notwithstanding the 
use of atropine three times a day.

19th.—Took a sixteenth of a grain of morphine at 10 p.m., 
and this he determined should be the last dose.

20th.—Took twenty grains of trional at 8 p.m., and 
continued its use, with good results, for seven days. His 
general condition was now much improved; though by no 
means rid of a great "hankering" for an occasional dose of 
morphine, he never after resorted to its use.

In a few days he was in apparently perfect health, and able 
to combat any morbid desires by saddling his horse and 
joying a brisk gallop over the country roads, the weather remaining 
remarkably fine until Christmas.

21st.—I left him, after congratulating him on the successful 
termination of his experiment.

He expressed himself as quite confident of his ability to re-
sist future temptation, and I had no doubt of it whatever. 
Certainly any future desire can not be compared in intensity to 
those which he had already so successfully combated.

I never before met a person habituated to the use of 
from three to four grains of morphine per diem who could 
rid himself of the habit in the short space of ten days under 
self treatment, or, in fact, any other kind of treatment.

I look upon his success as being due almost entirely to 
his strength of will, aided perhaps by an almost Crom-
wellian faith in the Almighty; and therefore believe that 
he would have succeeded under any treatment, provided 
that it were of a rational character.

Therefore, ending as I began, I regard it as an excellent 
illustration of the predominance of mind over matter.

RATIONAL

THERAPEUTICS OF CHOLERA INFANTUM.

By GUSTAVUS BLECH, M.D., 
ST. LOUIS.

No strict rules can be given for the treatment of dis-
ease. It is for this reason that so many physicians say 
we do not treat a disease, but we treat an individual. True 

enough, we treat the individual, but what we have most of 
all to consider is the disease. The individual will dictate 
us alterations and modifications in our treatment.
A general plan of treatment may be outlined, however, and I will try to do so in regard to one of the most fatal diseases of babyhood—cholera infantum.

There is a certain philosophy in therapeutics which I would frame in the three following rules: First, remove if possible the disturbing causes; second, treat symptoms which per se are liable to endanger the life of the patient; and third, sustain vitality.

As said before, the therapeutics which is based upon the etiology and pathology of a given case is the only one to be employed.

Now, the etiology of cholera infantum is not so obscure as asserted by a good many authors. Whether or not of microbial origin, one thing is sure—it is due to a chemical decomposition of food, causing an inflammatory condition of the digestive and alimentary canal.

Clinical experience, furthermore, shows that this disease is of a grave character, producing death in a large proportion. Heat per se is not the immediate cause of this disease, but it influences its course considerably. Therefore, gastric or intestinal disturbances in summer demand a closer attention than those which occur during the colder season. Cholera infantum is a disease met even in the palaces of the rich, although not so often as in the tenement houses of the poor, which fact proves again that bad air, filth, and lack of ventilation are also of a predisposing influence, as well as an obstacle to a quick cure. The mortality in the tenement houses is larger than that of the richer parts.

If we consider the aforesaid, we shall first of all, as regards the treatment of this disease, have to restrict diet.

As soon as called to a case of cholera infantum, prohibit for the first day any food whatever. Mothers have no right to nurse the little patient either. Strict instructions must be given in that direction, because the timid mothers are often inclined to quiet the crying babies by putting them to the breast.

Remedies are of very little value. Beginning with calomel, salol, and all the newer antiseptics, finishing with subnitrate of bismuth—they have all proved a failure, for none of them work quickly enough.

The treatment as outlined by Dr. Elmer Lee, of Chicago, in his cases of typhoid fever, proved a success in my hands during last summer, and under this treatment I have lost only one patient out of twenty three, while the monuments of my skill exercised during the year 1893 are decorating the cemeteries of the State of Connecticut.

So far as I knew, the best antiseptic (which has also a strong tendency to reduce local inflammation) was peroxide of hydrogen (medicinal) until hydrozone was used by me. Hydrozone being twice as strong as Marchand’s peroxide of hydrogen (for economical reasons), the latter drug is preferred by me. This remedy can be administered internally as well as externally.

I add a tablespoonful of hydrozone to a pint of water for washing out the stomach. The vomiting ceases after the first washing as a rule. If necessary, this procedure can be repeated. If the vital power of the little patient is not too low it can produce no harm. But in every case, no matter how far advanced, I do not omit an irrigation of the bowels, for which purpose I use a soft rubber catheter attached to a common bulb syringe. The catheter is introduced as high in the colon as possible. It is unnecessary to say that the water must first be sterilized. I do not agree with Dr. Lee in using hot soap water. On the contrary, I use cold water, and add to each quart about two ounces of hydrozone. The improvement after the first or second irrigation is marked. If necessary, these irrigations can be repeated every two hours.

Among other remedies there are only two to be employed, morphine and strychnine. Both ought to be administered hypodermically. Their indication is too well known and they are about all we need. No antipyretics should be given. If the fever is very high and if the irritation of the bowels does not reduce it, the whole body should be washed with alcohol.

The diet for the next twenty-four hours should be very light indeed. Sweet, strong Russian tea is all I allow.

Each individual case will teach us when food can be allowed again.

Since the adoption of this mode of treatment I have met with the most remarkable success, and no honest practitioner should refuse it a trial.

11 N. Broadway.

A UNIQUE METHOD OF MASTURBATION.
AND AN ACCIDENT THEREFROM.

By A. KIDDER PAGE, M.D.,

BOSTON.

J. O’B., nineteen years of age, single, came to my office at 12.30 A. M., January 4, 1895, and gave the following history—i. e., while practicing masturbation two hours before he had met with a very peculiar accident.

As had been his custom for some years, he had used a bottle to assist him in the “act,” but had never met with any difficulty until the present time, when his penis had got stuck in the bottle. Upon examination I found the penis tightly incised within the “neck” of the bottle, the glans and prepucce protruding through the “neck.” The prepucce was very edemasous; the glans was cut for about an inch in circumference from coming in contact with the sharp edges of the glass (he having broken the “body” of the bottle before coming to my office). The bottle was that of a quart size, with a neck three inches and a half long and seven eighths of an inch in diameter at the top.

It was impossible to move the “neck” in any direction, so tightly was the penis incised. I first packed the parts in ice, thinking I might be able to reduce the venous engorgement, but after fifteen minutes’ trial with this method my results were unsuccessful. I did not attempt to break the “neck” with a hammer for fear of injury to the organ. I finally packed the pubic end of the penis in ice, and then, after three or four minutes, I was able to insert the point of my bone-forcps blade between the penis and “neck,” and to cut it away piece by piece. I kept the parts covered with towels to prevent the glass from lying about.

Small particles of glass were profusely distributed upon the penis and under the prepuce; these I finally removed with the aid of a fountain syringe.

LEADING ARTICLES. 273

THE NEW YORK MEDICAL JOURNAL,
A Weekly Review of Medicine.
Published by D. APPLETON & CO. Edited by FRANK P. FOSTER, M.D.

NEW YORK, SATURDAY, MARCH 2, 1895.

RIGA'S DISEASE.

In the Presse médicale for January 26th M. F. Brun reports a case of the affection known as Riga's disease, the first, he thinks, thus far published in France, where it is known only by an analysis of a former work by Fede, which appeared in the November, 1893, number of the Revue des maladies de l'enfance; by a new and important communication made by Fede at the International Medical Congress in 1894, which was published in the Mercerei médical for June 20th; and by an abstract of this communication published in the Médecine infantile for August 15th.

What at first seems to lend a peculiar character to this affection, says the author, is the fact that, on the one hand, it has been observed almost exclusively in the southern provinces of Italy, where it seems to be endemic, occasionally attacking all the children in a family, so that it has been considered by some to be hereditary and congenital affection. On the other hand, it is observed when the first teeth make their appearance, apart from whooping-cough, sometimes in children whose general health shows nothing wrong, sometimes in cachectic children who are exhausted by ordinary attacks of gastrointestinal catarrh. With regard to any point that the serious and the benign cases may have in common, which may be considered as the proper character of the disease, it is the production, at the level of the frenum of the tongue, of a prominent fungous excrescence covered with a whitish exudation diphtheritic in appearance. The author recently had occasion to observe a case which seemed to him to correspond exactly with the descriptions given by the Italian physicians. The patient was a child, fourteen months old. It had never shown any symptoms of disease; it had never vomited or had diarrhoea, and it had not had whooping-cough or any convulsive attacks of coughing. The first teeth had made their appearance when the child was ten months old, and shortly after the eruption of the two lower central incisors the mother had noticed a small tumor under the child's tongue, which had steadily increased in size, but without having had any unfavorable effect on nutrition. The child's condition appeared to be excellent; there was no trace of rachitis, and this sublingual lesion, which seemed to be the only indication of disease, showed the following characteristics: Situated on the lower surface of the tongue, it was not visible unless the tongue was raised: it had the appearance of a tumor and was from four to five millimetres in height. It lay exactly in the median line, on the frenum, the anterior part of which it occupied, reaching as far as its lingual insertion, on each side of which could be clearly distinguished—and altogether independent—the openings of Wharton's ducts.

The tumor was firm and parchmentlike, and the hardness extended to the right and to the left somewhat beyond the protruding mass. With regard to the color, it varied in the center and at the periphery, where it was of the color of the lingual mucous membrane, while the central part assumed a whitish aspect owing to the presence of an exudation which became detached when it was rubbed gently with a tampon of cotton. When this was removed there was seen to be an ulcerated surface, villous and bloody, which, twenty-four hours afterward, was again covered with a false membrane. There were no other lesions of the buccal mucous membrane and no submaxillary or supra-hyoid ganglia. For several days applications of tincture of iodine were made to the surface of the tumor, but not obtaining any results from this, the author resorted to excision. A broad denuded surface was left after the excision, which he cauterized. On the following day the child's condition was normal, and cicatration followed without any particular incident.

After the excision pieces of the tumor were sent to M. Letulle, who made an examination of them. The results of this investigation are given in detail in the following account which he sent to M. Brun: "The sections, which were made perpendicularly to the surface of the piece removed, showed the successive layers of the buccal mucous membrane that had undergone various alterations: 1. The conjunctivo-vascular tissue of the mucous membrane was gorged with blood-vessels, mostly capillaries, very much dilated and lined with normal endothelia, several of which showed evidence of carciogenesis. The connective-tissue spaces, distended by a lymph that was somewhat rich in white cells, did not contain any kind of microbe. 2. The epithelial layers of the mucous membrane rested on a series of long conjunctival papillae amply provided with capillary vessels, which were larger than usual. The proof that the dermal papillae which corresponded to the tunneled mass were hypertrophied, was the condition of the derma on the borders of the specimen; there the papillary protuberances were not half so numerous as in the center of the hypertrophied mass. It was the same with the epithelial layers, so that from this point of view the edges of the tumor and its center were different in the same specimen. On the edges the pavement epithelium were accumulated in thick bands, terminated by a collection of nucleated epithelial cells, flattened, and mucous—denser or than at the surface of the normal buccal mucous membrane. Between the hypertrophied papillae the epithelial elements, which were very broad, were deeply buried, without however, having passed at any point the normal limit separating them from the dermal tissue. There was not, then, in these hyperplastic zones, which were like the border of the tumor removed, any trace of a neoplastic epitheliomatous production. There were not, either, any sufficient characteristics to warrant the application of the term papilloma to this dermo-epithelial overgrowth; it was, at the most, an hypertrophy of the mucous membrane in all its parts, and the causes of this hypertro-
trophy were shown by a study of the center of the mass, where the condition of the parts was different; there the derma was ulcerated, at least demounded, at a great many points. The papillae were abraded, some also had disappeared, and all the epithelial layers had been shed and been replaced by a very characteristic fibrino-leucocytic exudation. The false membrane which thus became attached to the derma of the mucous membrane extended here and there on the epithelial layers of the periphery, showing a very characteristic aspect, the diphteritic false membrane covering nearly the entire tumor. The layers of fibrin were formed at the expense of the epithelia and of the leucocytes which were exuded; the microscopical examination of the sections showed this very plainly. They were thick and dense, and their surface was covered with leucocytes, mucus, and microbes. The sections, treated by Wegert's method, showed two very distinct kinds of micro-organisms: 1. Long bacilli, rather slender, susceptible to Gram's solution, and situated only on the surface of the false membrane, into which it scarcely penetrated. 2. There were micrococi, round, slender, often in diplococci and in round masses, sometimes also in chains. These microbes were sunk in the surface in the deepest layers of the false membrane, without, however, ever going so far as the layers of fibrinous exudation; the points where they disappeared were always nearer the surface than the derma, to which the streptococi were not confined at any point. To sum it all up, there was not a tumor. It consisted of a chronic hypertrophy of the buccal mucous membrane, and was purely inflammatory. The center of its surface was ulcerated and covered with fibrinous false membranes which were infiltrated with microbes, but the microbes did not seem to have played any part in giving rise to the exudates."

It is not on one fact alone, says M. Brun, that we can rely in order to determine exactly the nature and the pathology of Riga's disease. The foregoing observation, however, presents certain features which are, he adds, not without importance. Without doubt, he says, he has seen the affection which has been described in Italy under the following names: Necrosis by compression (Ridola); small, pearly, fibrinous neoplasm (Pandolfi); pearl-colored neomembrane due to internal infection (Riga); sublingual production or Riga's disease (Fede). The descriptions given by these different authors and that cited above are altogether identical, says the author, and M. Letulle's histological examination is itself an exact reproduction of Fede's descriptions; there are the same lesions which were observed by Boccardi in two children who had a grave form of the disease, which terminated fatally.

In the author's case the sublingual lesion had no subsequent effects on the general health, although it had been growing for four months before he saw it. He thinks it is rational to admit, judging from the results of the histological examination, that it was a question of a local lesion, a sort of traumatic ulceration directly connected with the rubbing of the inferior surface of the tongue on the sharp edges of the two lower incisors, the repeated friction being considered as the probable cause of the papillary appearance of the ulceration. Must we look, asks M. Brun, for different interpretations in cases where the buccal lesion is observed in cachectic children, who have gastro-intestinal troubles which often end in death, and see in this, as Pianese did, a true infectious disease characterized on the one hand by general symptoms and on the other hand by a local lesion, the sublingual production, which would seem to be the means of entrance for infection or its particular localization? The undeniable fact that the tumor of the frenum presents clinically and histologically the same characteristics in healthy children and in cachectic children hardly favors this hypothesis, and until there is more conclusive information M. Brun thinks, with Fede, that it is natural to suppose that Riga's disease is more frequent in cachectics because their tissues are less resistant to the irritating causes, and because this disease only borrows an apparent gravity from the conditions under which it is sometimes produced.

THE PROPOSED HOSPITAL FOR PAY-PATIENTS WITH SCARLET FEVER OR DIPHTHERIA.

The project of establishing pay-hospitals in New York for the benefit of persons attacked with acute infectious disease under circumstances that are incompatible with their remaining in hired rooms has often been discussed, and we have advocated it strenuously. The difficulty of obtaining suitably situated property to be devoted to such a purpose has heretofore stood in the way of its execution, for whenever a site has been seriously considered the plan has encountered vigorous opposition on the part of the owners and occupants of neighboring property. Of course, there is no reasonable ground for such opposition, but so long as prejudice and narrow mindedness and selfishness are as prevalent as they are now and always have been it will defeat many a noble plan and humane purpose.

Quite recently, however, we are glad to be able to say, a piece of land has been spoken of that seems not to be in any way subject to the control, direct or indirect, of persons hostile to the proposed undertaking. It is situated in East Sixteenth Street, near the East River, and it is under the control of the Health Department of the city. It is in the immediate neighborhood of the Willard Parker Hospital, in which sick persons of the sort in question are cared for now. The Willard Parker Hospital is well conducted—indeed it is a credit to the city—but necessarily it does not afford the luxuries that well-to-do persons feel themselves entitled to enjoy so long as they are able and willing to pay for them.

To start the enterprise, a generous lady, Mrs. John W. Minturn, has offered the sum of $25,000, which she has at her disposal, to be applied to the building of the proposed hospital, provided the board of health will give the land for it to stand on and will co-operate with a board of trustees representing the subscribers to the endowment—for further substantial contributions are confidently expected—in managing the hospital. Mrs. Minturn's humane proposition has been laid before President Wilson, of the board of health, in a letter written by Dr. John W. Brannan, to whose encouragement and tact, if we
MINOR PARAGRAPHS.—ITEMS.

THE PHYSICIANS’ MUTUAL AID ASSOCIATION.

The New York Physicians’ Mutual Aid Association, of the various steps of whose good work it has frequently been our pleasant duty to make mention, has lately given a token of its prosperity of a kind that we do not remember to have observed before. It has paid an assessment out of the surplus funds, and thus avoided calling on its members.

ITEMS, ETC.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending February 26, 1895:

The American Medical Association.—The secretary of the Section in Neurology and Medical Jurisprudence, Dr. T. D. Crothers, of Hartford, Conn., has issued a circular calling for short papers on Epilepsy, Medically, Surgically, and Therapeutically; Hypnotism and Mental Therapeutics and their Medical Legal Relations; and Electricity—some New Therapeutical Relations and Questions of Treatment.

The Death of M. Alphonse Guerin, of Paris, is announced as having taken place on Thursday, February 21st. He was seventy-eight years old.

The Cleveland Medical Society.—The meeting of February 22d was devoted to the antitoxin treatment of diphtheria. The proceedings included papers by Dr. A. P. Ohlmacher, Dr. William T. Howard, Jr., and Dr. A. W. Hopkins, of Ashxia.

Army Intelligence.—Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from February 10 to February 23, 1895:

Tilton, Henry R., Lieutenant Colonel and Deputy Surgeon General, is announced as Medical Director, Headquarters Department of Dakota.

Godfrey, Guy C. M., First Lieutenant and Assistant Surgeon, will proceed without delay from Fort D. A. Russell, Wyoming, to Fort Omaha, Nebraska, and report for temporary duty.

Byrne, Charles C., Colonel and Assistant Surgeon General, is relieved from duty as Medical Director, Headquarters Department of Dakota, and announced as Medical Director, Headquarters Department of the East.

Birmingham, Henry T., Captain and Assistant Surgeon, is relieved from duty at Fort Grant, Arizona Territory, and ordered to Fort Trumbull, Conn., for duty, relieving Walker, Freeman V., Captain and Assistant Surgeon. Captain Walker, on being thus relieved, will proceed to Fort Grant, Arizona, and report for duty at that post.

Fisher, Henry C., First Lieutenant and Assistant Surgeon. The extension of leave of absence granted is further extended one month.

Society Meetings for the Coming Week:

MONDAY, March 4th: New York Academy of Sciences (Section in Biology); German Medical Society of the City of New York; Morrisania Medical Society, New York (private); Brooklyn Anatomical and Surgical Society (private); Corning, N. Y., Academy of Medicine; Utica, N. Y., Medical Library Association; Boston Society for Medical Observation; St. Albans, Vt., Medical Association; Providence, R. I., Medical Association (annual); Hartford, Conn., Medical Society; South Pittsburgh, Pa., Medical Society; Chicago Medical Society.

TUESDAY, March 5th: New York Neurological Society; New York Obstetrical Society (private); Buffalo, N. Y., Medical and Surgical Association; Elmira, N. Y., Academy of Medicine; Ogdenburgh, N. Y., Medical Association; Syracuse, N. Y., Academy of Medicine; Medical Society of the County of Herkimer (annual—Herkimer, N. Y.); Baltimore Academy of Medicine; Medical Society of the University of Maryland (Baltimore); Hudson, N. J., County Medical Society (Jersey City); Androseccgin, Me., County Medical Association (Lewiston); Essex, Mass., South District Medical Society (annual—Salem).

WEDNESDAY, March 6th: New York Academy of Medicine (Section in Public Health); Society of Alumni of Bellevue Hospital, New York; Harlem Medical Association of the City of New York; Medical Microscopical Society of Brooklyn; Medical Society of the County of Richmond ( Stapleton), N. Y.; Penobscot, Me., County Medical Society (Bangor); Bridgeport, Conn., Medical Association.

FRIDAY, March 8th: Yorkville Medical Association, New York (private); Brooklyn Dermatological and Genito-urinary Society (private); German Medical Society of Brooklyn; Medical Society of the Town of Saugerties, N. Y.

SATURDAY, March 9th: Obstetrical Society of Boston (private).
Marriages

James—Jennings.—In New York, on Wednesday, February 20th, Dr. Walter B. James and Miss Helen G. Jennings.

Died.

Dubois.—In Portsmouth, N. H., on Sunday, February 24th, Medical Inspector Frank L. Dubois, of the navy, aged fifty-seven years.

Forbes.—In New York, on Wednesday, February 20th, Dr. Lucy S. Forbes, in the thirty-second year of her age.

Magee.—In New Orleans, on Wednesday, February 13th, Dr. John Milton Magee, aged seventy-four years.

Porchon.—In Pinopolis, S. C., on Thursday, February 14th, Margaret Bentley, wife of Dr. F. Peyre Porchon.

Letters to the Editor.

The First American Symphysiotomies.

Brooklyn, February 24, 1895.

To the Editor of the New York Medical Journal:

Sir: In a recent number of the Philadelphia Medical News appeared an article under this title. It was published as an editorial, but was evidently inspired, if not mainly written, by the eminent statistician, Dr. Robert P. Harris. It places on record three symphysiotomies said to have been done before Pinard, of Paris, first operated.

It is stated that Dr. Joel O. Williams, now living in William Penn, Washington County, Texas, a town of twenty-nine inhabitants, did three public sections, one in 1889, one in 1884, and one in 1889. An humble practitioner in an obscure settlement of less than a score and a half of people professes to have been the first in all the world, outside of Italy, to follow the example of Morisani. Yet not a particle of medical evidence is adduced to support the allegations of the claimant. No other physician was present at the alleged operations, nor is the testimony of any of the doctor’s colleagues invoked in proof of the truthfulness of his assertions. The acceptance of these reports is based in one case on the affidavit of the woman said to have been operated upon, and in another on that of an alleged lay witness. Coggin’s claim, it will be remembered, rested on similar affidavits, a method of proof for which a physician in good repute among his fellows could have no use in substantiation of a mere scientific statement of medical facts.

Of one of his cases Dr. Williams says, “the pelvis was so contracted transversely that it was with some difficulty that two fingers could be passed,” a condition in which delivery by symphysiotomy would have been clearly impossible. Yet the child, he tells us, was extracted by forceps and saved, and that, too, after the mother had been for two or three days in labor and for thirty-nine hours in convulsions. Singularly enough, no laceration, hemorrhage, sepsis, or other operative complication appears to have occurred in any of these cases.

Brilliant as were these successes, nothing was known of them, in all these years, by the local profession. Remarkable as was the surgical genius implied in so bold a departure as symphysiotomy would at that time have been, especially in a rural district, Dr. Williams’s fellow practitioners, as diligent inquiry has shown, did not till now know that he made any pretense to operative work of any kind. Reputable physicians in the two counties in which the doctor has resided, including members of the State board of medical examiners, denounce the story as preposterous. Not one can be found who believes it. More than that, recent investigation by the local profession, as I am credibly informed, has disproved it.

It is to be regretted that our distinguished American statistician should have lent his indorsement to such ill-founded claims as this and the Coggin recital. Until these reports of early American operations can be made to bear at least the semblance of truth, the credit for the general revival of symphysiotomy must be accorded to Pinard, of Paris. So far as yet appears, he performed the first modern public section outside of Italy.

Charles Jewett, M. D.

Separation of the Lesser Tuberosity of the Head of the Humerus.

Morgantown, W. Va., January 25, 1895.

To the Editor of the New York Medical Journal:

Sir: I desire to report a case of separation of the lesser tuberosity of the head of the humerus. A boy, seventeen years of age, fell from the roof of a barn to an oak floor, eighteen feet below, and remained unconscious until picked up some minutes after. His shoulder was enormously swelled and there was a fracture of the shaft of the humerus at about the middle. The fracture was treated with good results. Movement at the elbow was practiced every day throughout the treatment. When the dressing and shoulder cap were removed a bony prominence could be seen and felt under the skin coming part way through the substance of the deltoid over the site of the lesser tuberosity. It had united again with the head of the humerus, inasmuch as it rotated with the head. Complete loss of function of the deltoid existed at this time and is not better now, ten weeks after. There is a nail-like process of bone projecting from the site of the lesser tuberosity through the substance of the deltoid. I can only find three cases of this character recorded.

There was complete sudden jaundice of the entire cutaneous surface of the boy when he was found. This cleared up in about ten days under small doses of Epsom salts. The boy was so stupid that he complained very little of pain during manipulation of the fracture.

James W. Hartigan, M. D.

Proceedings of Societies.

The New York Neurological Society.

Meeting of Tuesday, January 8, 1895.

The President, Dr. Edward D. Fisher, in the Chair.

A Case for Diagnosis.—Dr. Greene M. Hammond presented a girl, aged thirteen years, one of a pair of twins and poorly developed. There was nothing of importance in either her personal or her family history. For several years past her physician in the West, where she lived, had noticed a peculiar hardness of the muscles underneath the skin. This hardness was most pronounced in the muscles of the face and back of the neck and in those of the thorax and arms. When the muscles were relaxed and at rest the condition was not so pronounced. It did not interfere with the child’s motions, as she was able to jump fences and walk and run at pleasure. There was neither atrophy nor hypertrophy of the muscles. The child was well nourished and felt perfectly healthy. There was no discoloration of the skin or any coldness of the extremities. The strength
Acute Arsenical Poisoning, with Subsequent Multiple Neuritis.—Dr. Philip Meirwitz presented the case of a young man, aged nineteen years, who had inadvertently swallowed a large dose of arsenious acid, a teaspoonful (about seventy grains by weight). Immediately perceiving his mistake, he had forced himself to vomit by thrusting his finger into the pharynx, but the vomiting had not been very copious. Three hours after the ingestion of the poison severe pains in the stomach had come on, accompanied by vomiting, and this had continued for three days at intervals of from five to ten minutes. Food could not be retained, and he had come to feel an intense thirst. A physician who had been called had prescribed iron, but this had not been retained. The pain in the stomach had lasted for six days; the pulse had grown weak, the urine had been bloody, and the passage had caused considerable pain. The bowels had remained costive for four days. On the second day after the poisoning the patient’s sight had become affected. On account of the weak action of the heart attempts to sit up in bed would result in syncope. There had also been temporary deafness and tinnitus aurium, with hemorrhage from the ears, followed by a discharge of pus. On the fourth night after the poisoning the patient had become delirious and had hallucinations of sight; this had lasted for two days. The tongue had been blistered and swollen; the lips, eyes, and face oedematous. With the exception of a few pimples on the face, there had been no skin eruption. He had had a severe, burning headache, which had been difficult to relieve. On the seventh night he had entered into a condition of collapse, but had rallied the next morning. On the ninth day the stomach had tolerated a little food, and on the eleventh day he had been able to leave his bed. He had lost about twenty pounds during his confinement. At the end of the third week severe, continuous pains had manifested themselves in the legs, and three days later in the feet, which had become swollen. He had never had any pains in the arms, but some tingling in the hands. The condition of his legs had gradually become worse, until he had been unable to walk without the aid of crutches. On October 15, 1894, when he first came under Dr. Meirwitz’s observation, an examination was made with the following result: The patient’s gait was that of an ataxic; the legs were lifted high, to enable the toes to clear the ground, and were brought down with a stamp. The feet drooped and were cyanosed and cold; there was marked tenderness to pressure of the feet, legs, and thighs; the muscles of the leg were atrophied; there were involuntary contractions and twitches in the calf muscles. The foot, patella, and cremasteric reflexes were absent. Control over the contents of the bladder and bowels was normal. There was an anesthetic of the feet to the touch, extending to a point immediately above the ankle joint; two inches above this there was an area of hyperesthesia. Both lower extremities showed pretty generally hyperesthesia to pain. On testing with hot and cold water, the feet were found to be markedly anesthetic, while the lower half of each leg was hyperesthetic. There was also decided anesthesia of the legs to both faradism and galvanism. The electrical tests showed the reaction of degeneration for both currents. In the upper extremities the hands were mainly affected, and the movements of the fingers were greatly impaired.

Dr. C. A. Herter said he considered the case an interesting one because it was comparatively rare to see multiple neuritis produced by a single dose of arsenic; it was not so uncommon to see it produced by the injudicious use of arsenic given for medicinal purposes. The case was also interesting because it enabled us to fix accurately the time when the influence of the drug on the peripheral nervous system had been sufficiently pronounced to give rise to actual paralysis. This period, in the case narrated, had been about two months. The speaker expressed the opinion that in many instances a multiple neuritis of toxic origin did not manifest itself until some time after the ingestion of the toxic substance had ceased. In one case that he had seen, that of a woman suffering from alcoholism, a neuritis had developed six weeks after the patient had been admitted into the hospital, during which time she had practically had no alcohol given her. Another point of interest was the manner in which the cerebral symptoms were produced in cases of arsenic poisoning or lead poisoning of long standing. In a case of the latter recently observed, an encephalopaty had developed after paralysis of all four extremities. Ordinarily this condition would be attributed to the action of the lead on the brain primarily, but, as the man had a nephritis of long standing, it was difficult to say, as it was in all these cases, whether the cerebral symptoms were due to the poison directly or were of uremic origin.

Dr. Mary Putnam Jacobi said that when we considered the enormous dose of arsenic that the boy had taken, and the comparatively small part of it that he seemed to have vomited afterward, it appeared probable that much of the poison had been stored up in the liver, and subsequently its way into the circulation. From the history of the case, it seemed almost incredible that so large a dose had been taken, as such patients usually suffered from violent gastro-enteritis, or else there was a condition of choleraiform collapse.

Dr. William M. Leszninny, in reply to Dr. Herter, said that in his experience cases of arsenical poisoning due to the administration of the drug medicinally were not very frequent. He had seen five or six cases of multiple neuritis due to the ingestion of a single large dose of arsenic.

Dr. Cabot referred to a case reported in Boston where a child had suffered from symptoms of arsenical poisoning, and it had been found on investigation that the material of the nurse’s dress contained a large amount of the drug.

The President said that in these cases of metallic poisoning it was impossible to fix any limit to the time when the signs of neuritis might come on, as the poison often remained stored up in the system indefinitely. This was shown in persons who had been exposed to lead, and who long afterward might be attacked with the symptoms of lead poisoning when potassium iodide was given to them. In one case of acute mercurial poisoning that he had seen a neuritis had developed within forty-eight hours after the ingestion of the poison.

Three Cases of Unilateral Lesion of the Spinal Cord were presented by Dr. Pearce Bailey. The first patient was a man, aged forty-seven years, a Norwegian. Soon after his arrival in this country, twelve years ago, he had been stabbed in the back of the neck, close to the skull, on the left side. He had been unconscious for three hours after the receipt of this injury and had been removed to the hospital. On regaining consciousness he had found himself hemiplegic on the left side. The fact that he was hemi-anesthetic on the right side had not been noticed until some time later. His head had hung limp upon his right shoulder, and for five weeks he had been confined to bed with his head in supports. At the end of that time the power had begun to return to the leg and still later to the arm. Complete return of muscular strength had not occurred in either, and, though the leg was better than the arm, both were stiff. Sensation in these limbs had remained normal. On the right side tactile sensibility was but slightly affected, while sensation for pain and temperature was so much impaired that ordinary cuts, bruises, etc., caused no pain unless they were very severe; he could hold a piece of ice in his right hand in-
The patient first complained of severe headaches in April, 1894. At that time her eyes were examined, and no changes were observed in the optic discs. The pain in the head was excessive, especially in the morning, and was located on the right side and posteriorly. She was somewhat stupid. Her speech was not affected. The pupil of the left eye was dilated, but reacted normally to light. Her vision was unimpaired. There was slight left paresis of the face; the tongue did not deviate; taste was normal. The thyroid gland was enlarged on the right side. The left arm and hand showed decided weakness. There was pronounced ataxia. Sensation was much diminished and impaired as to touch and pain. She was unable to distinguish between heat and cold. The lower extremities were not affected. There was no vomiting, and there were no convulsions; the pulse varied from sixty-five to seventy; the temperature between 97.5° and 98.5°. Her condition continued to grow worse, and the headaches persisted.

On July 21, 1894, when Dr. Fisher first saw the patient in consultation with Dr. Julius Rosenberg, there was marked paresis of the left side, with flaccidity and diminished reflexes. The sensory condition showed generally reduced response to all tests. The mental condition was somewhat affected, the patient appearing to be hysterical; this, in conjunction with the flaccid paralysis and the complete dragging of the foot on walking, made a diagnosis of hysteria probable. The paralysis, headache, and mental stupor gradually increased and the sight began to fail. On August 31st an examination of the eyes made by Dr. Carl Koller revealed left hemianopia and choked disc, with paralysis of the left abducens. A diagnosis was then made of tumor at the base of the brain, involving the right crus cerebri above the third nerve and compressing the right optic tract. On September 12th blindness was complete, with optic atrophy. The motor and sensory symptoms on the paralyzed side remained unaltered. The patient was subject to hallucinations of sight and hearing. A diagnosis of tumor involving the optic thalami was now made. The patient went into a condition of coma and died on September 16th. At the autopsy a large vascular tumor, the seat of a recent hemorrhage, was found involving the right optic thalami and compressing the optic tract on that side by its extension downward. The growth proved to be a glioma.

**Tumor of the Aqueduct of Sylvius.—Dr. Joseph Collins presented the case of a lad, eighteen years old, a plumber’s assistant, who had been admitted into the Hospital for Nervous Diseases on October 6, 1894. The lad had then stated that his illness dated from a fall which he had received about six months before, but he had afterward said that he had not been well for two years, having dull, sleepless feelings which his people had attributed to laziness. He had taken no interest in his work, and it had been with difficulty that he had been able to keep his place, although he had done so until four months before coming to the hospital. During these two years he had had attacks of dizziness, some headache, and occasional weak spells, but he had never lost consciousness. He continued to grow worse, and in July, 1894, he lost control of the bladder and became uncertain and somewhat staggering in gait.

On his admission into the hospital he was examined with the following result: He was a large, dull, overgrown-looking boy, with an expressionless face. If left undisturbed he sat in one position the greater part of the time, and showed very little interest in his surroundings. He understood perfectly everything that was said to him, and answered intelligently but slowly. His memory was fairly good. He was deficient in mental power and apprehension, and continuous mental exertion was beyond him. His gait was the characteristic inco-
dination of one very drunk. When he attempted to walk he staggered, reeled, then plunged, but saved himself before falling. The staggering was not confined to either the right or left. The patellar reflexes were normal. Sensation was unimpaired, but not very acute. Vision was good; the pupils reacted to light and accommodation. The ophthalmoscope showed choked discs, but not to a very marked degree. There was no ocular paresis or paralysis. The hearing was good. There was no defect of smell or speech. The patient's temperature was continually subnormal, and he complained that he could not get thoroughly warm. He complained of spells of severe headache. He frequently passed his urine in bed or in his clothing, but this seemed to be due not so much to paralysis of the sphincter as to a lack of interest in responding to the calls of Nature. There was no nausea or vomiting. There was no loss of flesh.

The patient's condition gradually grew worse, and on the morning of November 2d he was found dead in bed. The autopsy was made eight hours after death. The occipito-mental circumference of the head was twenty-five inches and three quarters; the occipito-frontal, twenty-five inches and an eighth. There were no evidences of meningitis. On cutting off the cerebrum, medulla,pons, and cerebral pedunules there was found a grayish, translucent mass filling the aqueduct of Sylvius and projecting backward like a tongue. Anteriorly, it reached as far as the splenium of the corpus callosum and the posterior commissure. The walls of the third ventricle were nearly destroyed, so that that and the lateral ventricle practically formed one cavity. After hardening the brain in alcohol it was seen that the tumor extended downward almost to the upper termination of the fourth ventricle. Cultures of the tumor for tubercle bacilli were made with negative results. Dr. Brooks and Dr. Schmitt, who had made the bacteriological examination, had expressed the opinion that the growth was tuberculous. In connection with his paper, Dr. Collins exhibited the specimen and a number of microscopic slides.

Dr. C. L. Dana referred to somnolence as a very important symptom in the diagnosis of tumors in the central part of the brain. In a discussion of this subject before the American Neurological Association some years ago, in connection with a case reported by Dr. Sinkler, the opinion had been quite generally expressed that in cases where the growth was located in the deeper portion of the brain, not in any particular locality, however, somnolence and hebcedume were much more pronounced than in cases where the growth was situated near the surface.

In reply to a question, the President stated that the patellar reflex in his case had been lost on one side only.

Dr. Heister said he regarded this as a rather remarkable feature of the case. In cerebellar lesions it was not uncommon to find one or both of the patellar reflexes absent, but with tumors of the brain in this region it was uncommon.

Dr. Leszynsky suggested that the loss of the reflex might have been due to inhibition. In a case of traumatic meningitis of the convexity of the brain that he had recently observed in a child, eight years old, there had been complete temporary loss of reflexes on both sides. This also had occurred in a case of meningitis subsequent to pneumonia.

PHILADELPHIA ACADEMY OF SURGERY.

Meeting of December 3, 1804.

The President, Dr. William Hunt, in the Chair.

A Dumb-bell-shaped Calculus which had been Partially Encysted, Removed by Lithotomy.—Dr. H. R. Wharton exhib-
to be the safest operation for all save those who saw many cases.

Two Cases of Extensive Destruction of the Integument cured by Transplanting Large Flaps.—Dr. William B. Hopkins presented the following cases: John J., aged thirty-two years, had been admitted into the Episcopal Hospital on November 9, 1888, with an extensive laceration of the elbow, involving the skin and the superficial and deep fascia. The injury had been caused by a centrifugal drier in a sugar refinery. A month later, December 7th, an ulcer occupying the entire circumference of the elbow, consequent upon the original loss and subsequent sloughing of integument, remained. It extended from the middle of the forearm to the middle of the arm, or about ninety-six square inches in area. The following operation had then been performed: A vertical flap five inches wide and nine inches long, consisting of skin and superficial fascia, the base of which occupied the upper left pectoral region, and the edges of which were nearly parallel, had been lifted from the chest and sutured around the elbow, the limb being retained in the Velpeau posture. Approximation of the enormous chest wound, though not complete, had been materially facilitated by the emaciation following so severe an injury, and consequent relaxation of the integument of the chest. At the end of four days the flap had been severed from its basic attachment to the chest, and the arm had been released from its constrained position. There had been epidermal sloughing of the flap, after its severance, which had caused considerable anxiety, but its deeper layers had soon been found to have formed a firm attachment. The patient had remained in the hospital two hundred and seventy-nine days. The limb would be seen to have healed perfectly, and to be amply covered with a soft, pliable integument permitting of complete flexion and extension, pronation, and supination; indeed, although it was not quite so strong as the right arm, its functions had been entirely restored.

Case II.—Anton D., thirty-three years of age, a fireman, had been brought to the Episcopal Hospital on October 25, 1892, with a railroad injury of his left foot. The extremity had been so caught beneath the wheel that it had been completely flayed, but, as none of the integument had been lost, it had been brought together by sutures. Sloughing, however, of the entire skin of the foot and ankle had occurred. On December 4th a flap two inches wide had been dissected from the sound limb, from the lower portion of the thigh to the lower third of the leg, a distance of fourteen inches, its base being left attached at the lower part. Carrying the lower portion along the outer side of the foot from before backward, the flap had been reflected upon itself around the heel, and its remaining portion carried forward on the inner side of the foot to the toes. It had been retained in this position by sutures carried deeply enough through granulation tissue to take a firm hold and through the reflected lower borders of the flap occupying the sole of the foot. With a Y-shaped splint ingeniously devised by Dr. Ferguson, which had kept the injured foot in a state of absolute fixation to the calf of the leg on the sound side, the patient, with remarkable fortitude, had kept his limbs in this constrained position for over three weeks (twenty-two days), when the base of the flap had been detached, the latter having become firmly adherent to the foot. Advantage had been taken of this opportunity to gain a little more integument by dissecting the flap farther down the leg instead of cutting it off square at the root. The patient had remained in the hospital six hundred and fifty-seven days, at the end of which period he had walked without a cane and with a foot whose function had been sufficiently restored to enable him to resume his laborious occupation of fireman on a vessel. The foot would be seen to be a very useful one, its plantar aspect being covered entirely by leg skin, as shown by the growth of hair upon it.

It would be observed in both these cases that there was a singular freedom from the contraction of a tightly drawn peripheral cicatrix, edema, impairment of function, and other evidences of impeded return circulation. This factor alone placed this method of closing large circumferential ulcers far in advance of the method by skin-grafting. Though the method of Thiersch and others, of allowing the flaps, before severance at one or both extremities, to become granulated, would have been applicable in the first case, it was very doubtful if so long a flap as that transplanted in the other case would retain its vitality throughout its length, even if left attached at both ends.

Dr. J. Ewing Mears asked Dr. Hopkins why, in the first case, he had selected the Velpeau position rather than that at right angles. This would have given better opportunity for keeping the parts clean. An interesting point was in regard to the transplantation of large flaps to cover denuded surfaces about articulations. Both the elbow and the ankle in these cases showed perfect preservation of function.

Some years ago he had had under treatment a patient in whom a large denuded surface had occupied the surface of the abdomen. It had been the largest raw surface that he had seen up to that time. It had followed a sloughing buba from a non-infecting sore. When he had been called to the case the ulcer reached from the crest of the ilium of one side to that of the other, and from the umbilicus to the pubes in the median line, and on the right side, where it had originated, it extended three or four inches down the anterior surface of the thigh. It had required ten months for this surface to close entirely. The ulcer had finally been covered with a cicatrix which had not been very tense. Occupying the region it did, it had not been so necessary that it should possess the properties which we had seen in the cases which Dr. Hopkins had presented, where the ulceration had occurred in connection with articulations.

Dr. Hopkins said that it had been desired to take the flap from the chest rather than from the abdomen, and in order to secure the requisite length of flap it had been necessary to bring the arm approximately into a Velpeau position.

Book Notices.

The latest contribution to the literature of hypnotism is from the pen of Dr. Cocke, of Boston. It is a very entertaining book for the general reader, and, as it was evidently intended for popular consumption, it fulfills its mission. It embraces the whole field of the ordinary phenomena of hypnotism, and is valuable as a compendium of current opinion on the subject; and its bibliography, barring a few mistakes in names and dates, is invaluable. But for the more advanced student of the science it will in some respects be somewhat disappointing. For instance, under the subtitle, How it is Done, one expects something more than a compendium of the common methods employed by others, complete as it is in that respect. The author's brief statement that he has found "the prerequisite to hypnotism to be voluntary obedience for a few minutes" evidently conceals more than it expresses, and means much more than the mere quiet passivity which all hypnotists enjoin. There is a principle underlying that statement which, had it
been clearly formulated and illustrated, would have rendered his book more valuable than it is to the professional reader.

Again, he has treated all too briefly that burning topic of the hour—hypnotism and crime. He does not believe that hypnotism can be successfully employed to induce the commission of a criminal offense; but he details two experiments only to prove his position. As these experiments constitute a new departure in this line, they deserve special consideration. It has been customary for hypnotists, when making experiments to prove that hypnotism can be employed for criminal purposes, to place a paper dagger in the hands of the subject with the suggestion that there is a person present whom it is desirable to slaughter, and the subject generally thrusts the supposititious dagger into the hypothetical man with great promptitude. The superficial observer immediately comes to the conclusion that such an experiment constitutes conclusive proof that, had the dagger been a real one, a homicide would have been the result. Dr. Cocke evidently does not regard such experiments as conclusive, and he has had the courage to substitute a real weapon for the usual pasteboard dagger, with the result that the subject could not be made to use it upon a living person.

Such an experiment, properly conducted, has evidential value, as it demonstrates the fact that the self-suggestion of a subject who is not a criminal is strong enough to resist a homicidal suggestion. In point of fact such an experiment, properly conducted, would be a crucial test, for the obvious reason that an experimental homicide committed in the laboratory is just as fatal to the victim as one committed elsewhere in obedience to a criminal suggestion. Dr. Cocke states that he has tried thirty or forty experiments of a similar character with the same result in each case. If this is true it owes it to science to detail every experiment, and to state distinctly what measures, if any, he adopted to eliminate the element of suggestion. For it is obvious that an experiment with a real dagger would possess no more evidential value than one with a paper weapon, unless it is clearly shown, not only that there was no oral counter-suggestion made, but that there was nothing in the environment to suggest to the subject that he was expected to disobey the homicidal suggestion. It is difficult to imagine how the "suggestions of the environment" could be successfully eliminated in a laboratory experiment. But if Dr. Cocke can show how to do it, his experiments would constitute demonstrative evidence that hypnotic suggestion cannot be successfully employed to induce the commission of crime. Otherwise they must be classed with the regulation laboratory homicides committed with paper daggers upon unoffending broomsticks, and, like them, would possess no evidential value whatever. It is to be hoped that Dr. Cocke will treat this subject more fully in a second edition.

OPHTHALMOLGY.

By Charles Stedman Bull, A. M., M. D.

The Cerebral Centers of Vision and the Intracerebral Visual Nervous Apparatus.—Violet (Rev. gén. d'ophtal., Dec. 31, 1893) believes that the hemianopia which complicates verbal blindness is due to a destruction of the deep intracerebral visual fibers. The most circumscribed cortical lesions capable of producing hemianopia or cortical blindness, according as they are unilateral or bilateral, are situated on the internal surface of the occipital lobe and radiate into the region of the calcarine fissure. The cortical center of vision occupies the entire extent of the internal surface; it is limited anteriorly by the internal perpendicular fissure, above by the upper border of the hemisphere, downward by the lower of the third occipital convolution, and posteriorly by the occipital pole. The fibers, after having traversed the parietal and occipital lobes, end at the lower portion of the external corpus geniculatum and pulvinar, and at the external surface of the latter, by rising as far as the middle third of the optic lamina. The cortical center of vision is not completely isolated, for numerous associated fibers connect it with the visual center of the opposite hemisphere, with the center of visual memory, and with the zone of speech. The fibers which unite the two visual centers of the hemispheres with each other are represented by the callosal fibers which pass by the pad or cushion of the corpus callosum. Those which connect the visual center of perception with the center of visual memory follow many paths; the most easily differentiated fasciculi are the transverse fasciculi of the cuneus and the transverse fasciculus of the lingual lobule. Those which connect the cortical visual center with the zone of speech are formed by the lower longitudinal fasciculi, and especially by the occipito-temporal portion of this fasciculus.

A New Operation in Glaucoma: Scleriritomy.—Nicati (Rev. gén. d'ophtal., Jan. 31, 1894) recommends the following operation with a very narrow knife: The blade, with cutting edge downward, is introduced in the sclero-corneal margin in the inferior angle of the anterior chamber, passed horizontally across the anterior chamber parallel to the iris, and is brought out through the sclerotic. The blade is then turned on its axis ninety degrees with the edge toward the iris. This makes in the sclerotic an incision perpendicular to the first, and the aqueous humor at once pours out. The blade is then rapidly withdrawn, and the iris is divided at its peripheral attachment throughout the length of the wound.

Tumor of the Occipital Lobe with Hemianopsia.—Pie (Rev. gén. d'ophtal., April 30, 1894) reports the case of a tumor of the embryonic nervous type, occurring in a young girl aged fifteen. It was developed at the level of the cuneus, lingual lobe, and fusiform lobe of the right hemisphere, having originated at the level of the fissure of the hippocampus minor. He draws the following deductions: 1. Hemianopsia, without being frequent, is not exceptional in cerebral tumors. It is of cortical origin or connected with a lesion of the conducting fibers. 2. If of cortical origin, it is caused by the development of a tumor on the internal surface of the occipital lobe, on the level with or in the vicinity of the fissure of the hippocampus minor. The hemianopsia is homonymous and bilateral, without hemiopic reaction, and is usually accompanied by the signs of papillitis. 3. The existence of a hemianopsia is of great topographical importance for the diagnosis of a cerebral tumor.

Treatment of Myopia by Dissection of the Transparent Lens.—Pfaeger (Rev. gén. d'ophtal., May 31, 1894) recommends the dissection of the lens in certain cases of extreme myopia, and gives the results of thirty operations. His patients varied from ten to forty years of age. The age of the patient was without influence upon the rapidity of absorption of the lens. The degree of myopia in these cases varied between ten and twenty-two diopters. The diminution of the refraction which followed the dissection was greater in the cases of extreme myopia than in those of a lower degree. The primitive visual acuity and the amelioration by the operation were better in cases of a moderate degree of myopia—less than seventeen diopters. In children he puts the limit for operation at nineteen diopters and in adults at twelve diopters. In all the cases in which the operation was done the visual acuity was increased, and in several cases it was more than doubled. He never operates on more than one eye at a time, and always uses Bowman's needle. He has never seen any bad result follow the operation.

Tubular Glio-angiiosarcoma of the Retina.—Van Dycke (Arch. d'ophtal., December, 1893) reports in detail a very interesting case of this nature occurring in a child aged two years. There were several types of vessels in the growth. 1. Capillaries in which the endothelium or the proper limiting membrane was intact, and the adventitia was in direct connection with masses of glioma cells. 2. Capillaries formed by a simple endothelial tube giving off short lateral buds destined and ectatic. In the vicinity of these teleangeiecitic capillaries the gliomatous tissue was especially exuberant. 3. Vessels more or less hyaline in structure surrounded by groups of cells. 4. Hyaline vessels still containing blood and in some cases thrombi. In some of these the globular degeneration noted by Kliebs as a prelude to thrombosis could be seen. 5. Vessels entirely hyaline in structure in process of complete atrophy.

Clinical, Bacteriological, and Therapeutical Studies in Ocular Diphtheria.—Sourdille (Arch. d'ophtal., January, 1894) calls attention to the value of a topical application in diphtheritic conjunctivitis consisting of glycerin, twenty grammes, and phenic acid, two grammes, as it is borne very well by the eye and produces but slight and transient pain. The lids are reared, and thorough irrigation is made with some antiseptic solution. After all discharge is washed away and bits of membrane or necrosed tissue have been removed, a tampon of cotton is soaked in the solution of glycerin and phenic acid, and with this all the diseased surfaces are smartly rubbed. The application may be made twice a day, care being taken to avoid touching the cornea.

Treatment of Trichiasis and Distichiasis by Advancement of the Upper Lid.—Fernandez (Arch. d'ophtal., February, 1894) advises the following operation: He incises the external commissure, detaches the upper lid for the height of a centimetre, and places beneath it a short flap detached from the temple. The commissure is then reunited. This method is based on the anatomy of the orbicular muscle, the fibers of which are inserted internally on the bone and externally in the skin. This arrangement renders possible the detachment and elevating the external extremity of the orbicular muscle without lessening its properties as a splincter.

Neuroses of Secretion of the Lacrimal Gland; Lactation and Dryness of the Conjunctiva in Exophthalmic Goitre.—Berger (Arch. d'ophtal., February, 1894) believes that the lactation occurring in exophthalmic goitre is not caused by the exophthalmia and the absence of winking. The lactation may precede for several years all the other symptoms of exophthalmic goitre, and may last for years after the exophthalmia has disappeared. Moreover, the dryness of the conjunctiva may appear at a period when the exophthalmia has disappeared. The lactation is due to a hypersensation of
the lacrimal gland, and the dryness coming on in the course of the same disease is caused by a diminution in the secretion of the same gland. The secretory nerves of the lacrimal gland are, in the beginning of an exophthalmic goitre, in a state of irritation, and it is only at a later stage of the disease that these nerves become parietic.

The Field of Observation in Ophthalmoscopic Examination with the Upright Image.—Guillot (Arch. d'ophtal., February and March, 1894) defines the field of observation as follows: The actual size of that portion of the retina giving the ophthalmoscopic image perceived by the eye of the observer, this eye remaining immobile, as well as the eye of the patient. When the patient is emmetropic, the field of observation increases proportionally to the sum of the apparent pupillary openings of the observer and the patient, and inversely to the distance between the eyes. The field of observation is weaker or smaller in the myope than in the emmetrope, and diminishes with the degree of the myopia. In hypermetropes the field of observation is greater than in emmetropes, and increases with the degree of hypermetropia.

Corneal Transplantation; The Causes of Failure and the Remedy.—Cole (Amer. Journ. of Ophthal., March, 1894) claims the following advantages for his method of operating: 1. It admits of the use of as large a graft as may be necessary, yet the elastic openings in the limbus, if properly made, will hold it in good position. 2. The elastic band also gives circular and uniform union without any bulging at points intervening between the flaps because of the size of the graft. 3. It furnishes the largest surface possible for union, offering the best opportunity for healing in a manner to allow the greatest freedom for the passage of nutritive elements through the lymph channels of the cornea itself. 4. Large additional channels of nutrition are afforded, without the intervention of any corneal scar, through the large conjunctival flaps. 5. The cicatrix is placed obliquely through the most vascular area in the border of the cornea, and therefore in the most favorable position.

Two Cases of Sarcoma of the Lacrimal Gland; Removal and Microscopic Examination of the Tumors.—Lawford and Collins (Roy. Lond. Ophth. Hosp. Rep., xiii, 4) report two cases of this nature, both in males. They conclude that in every case of sarcomatous growth involving the lacrimal gland, there is room for doubt as to whether the growth originated in the gland or spread to it from surrounding structures. In the two cases reported the situation of the new growth between the gland tubules, which were separated by it, inclined to the belief that the fibrous stroma of the gland was the starting point of the sarcoma.

The Condition of the Vortex Veins of Twenty Eyes enucleated for Primary Glaucoma.—Stirling (Roy. Lond. Ophth. Hosp. Rep., xiii, 4) gives an interesting report on these cases. In eleven of the twenty eyes the choroid showed inflammatory patches, but nothing abnormal was found in connection with the vortex veins except in three of the eyes examined. The choroidal inflammation always consisted of small but distinct aggregations of cells between the vessels, but not in the vessels themselves, not limited to any particular layer of the tissue, and never running into one another in such manner as to give rise to the appearance of a change affecting it throughout. In no case was the lumen of any choroidal vessel diminished by exudation pressing on it from without. In one case there was a slight inflammation round one of the vortex veins at its choroidal extremity. In a second case there was an inflamed patch in the wall and circumvessel sheath of a vortex vein in the sclerotic, and the lumen was partially filled by a blood clot; and in the wall of a vein just external to the sclerotic, and close to the vortex vein, was a markedly inflamed patch. In a third case there were patches of inflammation in the vein wall and circumvessel sheath, and in the choroid; in the lumen of the main vessel were circular bodies, about one fourth the size of a nucleus, which gave a bright reflex from their center. These were too large for any of the known coeoi, and the author was not able to determine what they signified.

Secondary Transverse Films of the Cornea.—Usher (Roy. Lond. Ophth. Hosp. Rep., xiii, 4) gives the results of his microscopic studies of these films as follows: 1. The antero-posterior diameter of the cornea is increased at the situation of the film. 2. A formation of laminated fibrous tissue is present at the anterior part of the cornea, between the epithelium and the normal situation of Bowman's membrane; in most cases this tissue contains a granular material. 3. Granular hyaline or entirely granular bands are found at the posterior parts of the new tissue, in some cases sharply distinguishing it from the substantia propria. These bands vary much in length, shape, and arrangement, but their breadth was that of a normal Bowman's membrane. The number of the granules in the bands varied considerably, and the more numerous they were the deeper was the logwood staining. The band is sometimes straight and sometimes undulating. 4. Where the hyaline granular bands exist, Bowman's membrane was never found in contact with the epithelium. 5. Degenerative changes were found in the epithelium at the situation of the film. 6. A portion of the film, treated with strong hydrochloric or acetic acid, showed by the evolution of bubbles that calcareous material was present.

Primary Sarcoma of the Orbit, with Notes on Twenty-nine Cases.—Stirling (Roy. Lond. Ophth. Hosp. Rep., xiii, 4) gives the following results of his investigations: The average at the time of the first appearance of the growth was twenty-eight years and two twelfths, and varied from three weeks to seventy-five years. Of the twenty-nine cases, 17.5 per cent, had received a previous injury to the orbit. Of the known duration before the first operation, the average was eighteen months; the shortest was three weeks; the longest was eight years. Recurrences were noted in seventeen cases, or 58.6 per cent., and the total number of recurrences was thirty-five. The average time elapsing between operations and recurrences was twenty months. The shortest interval was a day or two; the longest was thirty-eight years and a half.

In those patients who suffered from recurrences the tumors were found to be composed of round cells in fourteen cases; of mixed round and oval cells in four cases; of mixed spindle and oval cells in one case; and of simple spindle cells in eight cases. In four cases the primary tumor was composed of round cells, the recurrence of spindle cells; and in one case the primary growth was of mixed spindle and oval cells, and the recurrence of round and oval cells. Where the growth alone was removed without clearing out the contents of the orbit, ten cases in all, no recurrence had taken place in one eighteen months after the operation, and recurrence did at some time take place in the remaining nine cases.

In those instances in which all the contents of the orbit were removed, sixteen in all, there was no recurrence in seven cases.

The Anatomy and Pathological Physiology of the False Membranes of the Conjunctiva.—Sonnelle (Arch. d'ophtal., April, 1894) draws the following conclusions from his investigations: There is no essential difference, from an anatomical point of view, between a conjunctivitis and an interstitial conjunctivitis. Both are the result of the same process, which in one case is arrested in its course or aborted, either
from slightness of infection or from the resistance of the tissues, while in the other case it advances and continues, but always in the same sense. From a clinical standpoint it is well to preserve these two forms, the croupous and the interstitial, for in general they show a course and a gravity of prognosis very different from each other.

Injuries to the Eyes from Gunshot Wounds in the Temple.—Scheidlemann (Cvrbbl. f. prak. Aug., December, 1893) tabulates the injuries to the eye to be expected from gunshot wounds in the temple as follows: 1. Laceration of the optic nerve, with immediate blindness. 2. Internal hemorrhage and laceration of the inner coats of the eye, if the eyeball had been bruised by the shot. Vision may here be affected in varying degrees. 3. Paralyses of the ocular muscles, either isolated or in connection with the symptoms above mentioned. The shape of the eyeball is usually maintained, either because it usually lies in front of the course of the bullet, or because of its globular shape and its tendinous envelope.

Papillitis following Extraction of a Tooth.—Hermann (Cvrbbl. f. prak. Aug., December, 1893) reports the case of a child, aged five years, from whom a decayed tooth was extracted without an anesthetic. A few hours later he complained of falling sight, and the next morning he was entirely blind in both eyes. The ophthalmoscope showed marked papillitis in both eyes without hemorrhages. The cause was probably a hemorrhage at the base of the brain which pressed upon the chiasm and right abducens, due to the extraction of the tooth while the entire muscular apparatus of the boy was in a state of extreme tension.

Subconjunctival Sublimate Injections.—Gepner (Cvrbbl. f. prak. Aug., January, 1894) recommends the use of an ordinary Pravaz syringe, with the end of the needle somewhat flattened and sterilized in the flame of a lamp. He injects about one twelfth of a milligramme of sublimate at a dose. He first uses cocaine, and makes the puncture one centimetre deep in the conjunctiva and about one centimetre from the corneal margin. The little bleb formed by the injection may be caused to disappear by slight rubbing beneath the closed lids. A bandage is then applied for one day. Severe pain follows the injection, and lasts for several hours. The next day there is marked injection and considerable swelling of the conjunctiva, with extravasations of blood. At the point of injection the conjunctiva becomes adherent to the subconjunctival tissue and capsule of Tenon.

A Case of Movable Fibroma of the Orbit.—Goldzieher (Cvrbbl. f. prak. Aug., March, 1894) reports an interesting case occurring in a young man. In the left orbit there was a nodular tumor, which extended from the outer canthus nearly to the outer margin of the cornea, and was covered by the vascular conjunctiva. Diplopia appeared when the patient looked to the left. The tumor was shed out of the orbit without any difficulty through a simple incision in the conjunctiva. It was ovoid, tolerably hard, three centimetres long and two centimetres thick, and seemed to be encapsulated. It consisted of densely crowded connective-tissue fibers, with a few fusiform cells.

The Results of the Operative Treatment of High Degrees of Myopia.—Von Schröder (St. Peterb. med. Woch., 1894, No. 4) recommends the following operative procedures: Preliminary iridectomy; four weeks later, dissection of the capsule of the lens; a few days later, extraction of the swollen lens. The danger of the operation in myopic eyes otherwise normal is by careful antiseptic methods reduced to a minimum. Even in extensive degeneration of the choroid and retina there is but little danger of retinal hemorrhage. The changes in the eye induced by the operation do not increase the liability to detachment of the retina or to chorioiditis, to which these eyes are always exposed. Cases of myopia of more than D. 14., which do not bear glasses, may have the operation done, and as early in the life of the patient as possible.

The Effect of Antipyrine in Certain Forms of Atrophy of the Optic Nerve.—Valbude (Ann. d'oc., September, 1893) thinks that antipyrine by its dilating action upon the peripheral vessels may produce a favorable result in those forms of optic-nerve atrophy which depend upon a vascular alteration of the interstitial connective tissue which forms the stroma of the optic nerve; that is, in atrophy due to ascending or descending neuritis. The effect of this drug is so feeble and limited as to cause much uncertainty of a good result, even in favorable cases.

Perimetry by Means of Colored Pigments.—Ole Ball (Ann. d'oc., September, 1893) divides the alterations of the color-sense induced by disease into three classes: 1. Diminution of the color sense to the same degree for the four principal colors. 2. Diminution of the color sense for red and green, while that for yellow and blue remains normal. 3. The shades of green are confounded with blue, and those of yellow with red; at the same time the yellow and red appear deeper than the blue and green. The first of these alterations accompanies lesions of the optic nerve due to an interruption of conductivity and to circulatory disorders of the retinal vessels. The second accompanies certain forms of primary atrophy, such as those due to tabes and to nicotine poisoning. The third accompanies all affections in which the light sense is considerably diminished in a moderate light, as in affections of the external layers of the retina, such as choroidal retinitis, or retinitis pigmentosa.

Secondary Images.—Snellen (Ann. d'oc., October, 1893) gives the results of his investigations on this subject as follows: 1. An instantaneous illumination produces secondary images which present three different phases. 2. The first two phases are the more sharply defined the shorter has been the illumination. 3. The third phase appears only when there is complete absence of all external light. Objective light causes this secondary image to disappear. 4. During the fixation of a feebly illuminated surface an image is perceived which is successively bright and dark. These changes indicate the existence of retinal fatigue, followed immediately by re-establishment of the usual sensitiveness.

Pseudo-retinitis Pigmentosa.—Germain and Dianoux (Ann. d'oc., October, 1893) classify the anomalous observations of retinitis pigmentosa of the latter author in three groups:

The Visual Function and the Cuneus.—Brissaud (Ann. d'oc., November, 1893) draws the following conclusions from his investigations:

1. The radiating optic fibers, or sensitive fasciculi, are the best defined fasciculi of all the mass of the centrum ovale. Their origin in the opto-striated nuclei has been definitely settled. Their termination in the occipital region is equally satisfactorily
determined. They end in the inferior portion of the lingual lobe, from the posterior extremity of this convolution to the accessory hippocampus behind the amygdaloid nucleus. A certain number also pass into the falsiform lobule and even into the third occipito-frontal convolution.

2. Properly speaking there are no fibers of projection of the cuneus upon the nuclei of vision; or, if there are, they are so extremely few in number that their destruction could not alone suffice to produce hemiopia. The lesions of the cuneus alone are incapable of producing hemiopia by a rupture of the fibers of projection. If the lesions of the cuneus have this result, the mechanism of hemiopia is not that which is usually advanced.

Unilateral Central Disturbances of Vision and their Relations to Hysteria.—Knies (Ann. d'oe., January, 1894) gives a résumé of the symptoms as follows: 1. The diminution of the visual acuity is always present, but total blindness is rare. 2. Concentric limitation of the visual field is a constant symptom, but bears no proportionate relation to the degree of diminution of the central vision. 3. Dyschromatopsia is almost always characteristic. It is identical with the color sense of the periphery of the normal retina and with that of the central part observed in feeble illumination. It is analogous to that met with in atrophy of the optic nerve and in toxic amблиопia. The fields for red and green are considerably narrowed and in advanced cases entirely abolished. The dyschromatopsia is ordi-

narily proportionate to the narrowing of the visual field. The reaction of the pupil to light varies; in amблиопia it may be preserved or be entirely wanting. The reasons which point to a central origin of these symptoms are the following: Symptoms observed in hysterical patients and accompanied by other disturbances of sensibility (anaesthesia of the cornea, conjunctiva, and face) which are incontestably of central origin. These symptoms may appear or disappear without apparent cause; they may be provoked or suppressed by suggestion. They change from side to side after certain manipulations. Their intensity is variable and depends upon the attention of the patient. The faculty of orientation is preserved in spite of the limitation of the field. The retina and optic nerve are normal even after long duration of the functional troubles.

Two New Methods of Curing Ectropion due to Blepharitis and Senile Ectropion.—Fukala (Ann. d'oe., January, 1894) describes two operations which he maintains are new:

1. For ectropion due to blepharitis: The skin is dissected from the tarsus throughout its whole extent; a needle is introduced through the skin in the gap separating the tarsus from the skin, about four or five millimetres below the free border of the lid and from three to four millimetres from the external canthus. The needle is then passed through the corresponding portion of the tarsus, but very near its upper border. The needle is then passed again through the tarsus, three millimetres nearer the lacrimal punctum, and then again through the skin near the first puncture. The ends of the suture are then tied over a bit of cotton wadding or plaster. A similar suture is then introduced near the inner canthus. This operation resembles that of Gayet.

2. Senile ectropion: Fukala excises all the everted parts and sutures the skin to the conjunctiva, avoiding as far as possible the lacrimal punctum. A dressing and bandage are then applied and allowed to remain three days.

The Equality of the Retinal Images in Corrected Axial Ametropia and in Emmetropia.—Lagrange (Ann. d'oe., February, 1894) draws the following conclusions from his investigations: In axial myopia, as in hypermetropia, the correcting glass placed at the anterior focus has for its object the advancement or withdrawal of the nodal point for a distance equal to the excess or deficit in the length of the axis of the eye. This displacement of the nodal point may be established in an elementary manner by a geometrical demonstration.

This displacement of the nodal point enables us also to understand why the retinal images are equal both in emmetropia and in corrected ametropia.

**Purulent Chorioiditis with Streptococci occurring spontaneously in the Course of General Septicaemia with Purulent Arthritis.**—Veillon and Morax (Ann. d'oe., May, 1894) report in detail a very interesting case occurring in a man aged thirty-seven. This patient had a purulent arthritis as one of the results of a general medical septicemia, and in the course of this disease a suppurative chorioiditis was set up by the streptococci without any anterior affection of the eye and without traumatism. The examination of the pus from the joints and from the eyeball showed the existence of the streptococci. The method of entrance of the micro-organism into the circulation remained completely obscure throughout.

**A Rare Form of Bullous Conjunctivitis.**—Berry (Ophth. Rec., March, 1894) reports a case of this nature in a woman, aged forty-seven. About a third of the tarsal surface of the conjunctiva of each upper lid was marked by an irregularly stellate cicatrix. These cicatrices were superficial and only slightly puckered at their centers. One year previously the lids had been much swollen and painful for three weeks, during part of which time the patient could feel little bladders lying under them. This attack in the eyelids occurred contemporaneously with an eruption on the face and shoulders which was called dermatitis herpetiformis. The appearance of the conjunctival scars was very different from that of those caused by pemphigus.

**Blinding of the Retina by Direct Sunlight.**—Mackay (Ophth. Rec., March, 1894) believes that the first retinal function which is modified by a sunlight injury to the human eye is the capacity for observing after-images at the affected part. The whole phenomenon seldom lasts more than a few minutes, and its disappearance is followed by a prompt recovery of the normal retinal function. The persistence or reappearance, on closure of the eye, of a sun-image which does not rapidly undergo alterations in color may perhaps be taken as the mark of a retinal stimulation which has slightly surpassed the physiological limit, but at the same time it is an indication of cellular vitality at the injured part. It is an unfortunate characteristic of this affection that the injured eye is usually that which had previously the acuter vision. The state of the color sense at the injured part has not received much attention. The scotoma is positive and has generally been projected as a gray spot or luminous disc. The defect for colors extends over a larger area and is more profound than for white. The revolving movement and the oscillation complained of by some patients are curious accompaniments of the scotoma for which no satisfactory explanation has yet been given. The symptom is usually very persistent, and constitutes a factor to be reckoned with in framing a prognosis. As regards the ophthalmoscopic picture, if the case be seen within the first week, and the lesion be slight and limited to the fovea, only a little flattening and loss of the light reflex is likely to be found. During the second week there is a tendency toward increase of pigmentation from proliferation of hexagonal epithelium, and this may replace or obscure the signs of exudation.

The prognosis for a decided improvement in vision and a practical cessation of discomfort is, on the whole, favorable, but complete recovery is exceptional. The data to be considered in forming our prognosis are as follows: 1. The time which has elapsed since the accident. 2. The degree of impairment of visual acuteness for test types and colors. 3. The extent of the scotoma, and especially of the absolute area cou-
tained within it. 4. The gravity of the ophthalmoscopic changes. 5. The presence or absence of oscillating movement. 6. Metamorphopsia. 7. The local and general healthiness of the patient. 8. The refraction of the eye. 9. The natural pigmentation of the fundus.

As regards the treatment, the protection of the eyes from great alterations of light by the constant use of dark glasses with side pieces (London smoke, No. 3), and rest from eye work during the first month, is all that is indicated.

Rare Anomaly in the Retinal Circulation.—Axenfeld (KL. Mon. f. Aug., January, 1894) reports a rare form of abnormal circulation in the retina, occurring in one eye of a man, aged twenty-nine years. The development of the papillary veins was so slight that only a portion of the retina could have been nourished by them. Still, there was no sign of retinal atrophy, and, though the arteries were but slightly reduced in caliber, the veins were enormously distended. Both above and below the region of the disc there was a large vein which received numerous branches from the rest of the retina, and then ran, not toward the disc, but toward the periphery, and finally disappeared in the choroid.

A New Method of Operating for the Relief of Ptosis.—Pergens (KL. Mon. f. Aug., January, 1894) recommends the following method of operating: He makes a curved incision through the skin from one canthus to the other, just beneath the margin of the orbit, and dissected the skin free. At the upper margin of the incision he introduces a double-edged knife beneath the skin upward as far as the shaved eyebrow, and dissected the skin free from the subcutaneous tissue from one end of the eyebrow to the other. Close to the edge of the flap and in the median line he then introduces a suture armed with two needles, which are then brought out parallel to each other through the skin above the eyebrow. When these two lines of suture are drawn tight, the pedicle of skin with the lid is brought into the desired position and the two ends are then to be tied over a bit of rubber tubing. Similar sutures are inserted at the nasal and temporal sides of the flaps. An incision is then made from one end of the first incision to the other through the skin of the lid, parallel to the canthus and three millimetres above it, and the edges of the two incisions are brought together with five or six sutures, so that the oval flap of skin of the lid is covered by the skin flaps in the new position of the lid. Pergens maintains that this method of operating has all the advantages of Panus’s operation.

(To be continued.)

New Inventions, etc.

A FRONTAL SINUS DRILL.

BY A. WORRALL PALMER, M.D.

This simple instrument is presented to the profession because by its employment it is considered that the internal operation upon the anterior ethmoidal cells and frontal sinus is simplified and made much less dangerous than by the usual methods in vogue—e.g., by curette or spoon.

I desire to call attention to the following points in its favor: The burr a is four millimetres and a half in diameter, a size which will pass through the average anterior portion of the bulla ethmoidalis without cutting the os planum into the orbit. The burr is an improvement on the curette or spoon, as it cuts away a more even or smooth-walled canal through the ethmoidal cells. The latter rather digs or breaks away the thin cell walls, leaving irregularities in which the end of the flushing catheter may be caught, and sharp edges which may cut off the end of a rubber catheter if such is used for subsequent washing of the cavity. The writer has had a small portion of a French rubber Eustachian catheter almost severed in this way.

On the projecting extremity of a is a probe point, which in operating is placed in the outlet of the naso-frontal canal (after the anterior portion of the middle turbinated has been excised), and by it the course of such canal can be followed, thereby avoiding encroachment on the os planum and especially obviating the possible accident of passing through the thin or permeable portion of bone between such canal and the cerebral cavity. It is blunt at the point so that it can not be forced into such bone, still small enough to be insinuated into an obstructed naso-frontal canal that has been cocainized for the operation.

The curve of the cannula c is such that by resting the straight portion on the inferior margin of the anterior nares the probe and burr are forced against the mouth of the canal in the direction of the axis of the canal.

This cannula passes entirely through the handle, so that if desired, the instrument can be used for washing.

The handle e is of a convenient shape and size to hold in the same manner as a pencil.

The burr is connected by a cable passing through the cannula b and handle e to the revolving handle d. Manual motion by the operator’s hand is preferable to that obtained from an electric motor, because by it the cutting is more delicately and slowly accomplished.

The bone to be perforated consists only of several thin cell walls, and these, when diseased, are usually softened by necrosis, so that the rapidly revolving electric drill might crush through into the brain cavity.

By means of a thumbscrew on d, that handle can be removed, the burr and connecting cable withdrawn from the cannula b, and the whole thoroughly and antisepically cleansed.

While holding the drill in position, using the inferior margin of the anterior nares as a rest or fulcrum, the operator is cautioned to draw the handle downward, thereby urging the opposite end (burr) anteriorly, so making it almost impossible to enter the anterior cerebral fossa. At the same time, by a rotary motion of the handle, urge the burr toward the median line of the patient, thereby lessening the possibility of perforating the os planum.

The manufacturers, Tiemann & Co., are making an attachment by which it can be connected with an electric motor.

Miscellany.

The Action of Malakin as an Antipyretic and Antirheumatic.—To the February number of the Edinburgh Medical Journal Dr. Robert Abernethy contributes an article on
this subject, in which he says that he has used malakin in a number of cases of pyrexia of rheumatic and other origin, and has been struck with its good effects. Malakin, he says, is said to be a salicylideneparaphenetidinum which, in the presence of dilute mineral acids, is decomposed into salicylic aldehyde and paraphenetidinum. This decomposition taking place in the stomach, the salicylic aldehyde, on being absorbed, is, according to Schmiedeberg, oxidized into salicylic acid in the tissues of the body and can be recognized in the urine. The author gives the following case in detail, as it illustrates, he says, a troublesome condition occasionally met with in protracted cases of rheumatic fever: The patient, a woman, twenty-nine years old, was admitted into the hospital on May 12th. A few days before she had had a chill with fever and pain in the joints, beginning in the left thumb and soon spreading to nearly every joint in the body. The signs were typical of a severe attack of acute rheumatism, with copious sweat perspiration. The temperature was 101° F., and the pulse was 90. There were severe pain and swelling of various joints, particularly the knees and wrists.

At first salicin was given in doses of thirty grains every two hours, and this was continued until the 17th, without, however, having a very marked controlling effect on the symptoms. The pulse and the breathing became accelerated, and some consolidation was noticed at the base of the left lung. The temperature varied between 99° and 102°. Quinine sulphate was substituted for the salicin, but with no effect on the temperature, although the symptoms in the left lung entirely disappeared. The patient lost a good deal of flesh, and paraldehyde was administered in order to induce sleep. The joints began to improve, and on June 29th the right knee was the only one affected, but there was still a good deal of effusion in it. On this date, however, the patient had a sudden very severe rigor, and the temperature rose to 104° 8; there was copious sweating, with severe pain in the right knee joint. The ice-pack was applied and brandy given, with the result that the temperature fell to 101° 8 in five hours. Fever persisted, however, and the patient continued to lose flesh.

No albumin appeared in the urine, and the articular swelling began to disappear under blistering and rest. On July 7th the temperature rose again to 105° 4, with a rigor, but fell rapidly after sponging with ice-water and the administration of stimulants. These pyrexial attacks occurred from time to time, and toward the end of July the temperature curve assumed a more zig-zag course instead of its previous continued type. During the first part of August several attacks occurred, and after the 12th they took place almost daily.

On the 28th of August the author began the use of malakin and gave it to the patient in doses of fifteen grains three times a day, and at once there was a cessation of all pyrexia; the temperature became normal and remained so until the patient left the hospital. She was then quite well, fairly strong, and able to walk about the ward, and nothing remained but a faint systolic bruit accompanying, but not replacing, the first cardiac sound.

Dr. Abernethey was so convinced of the good effects of the drug in this case, after other antipyretics had failed, that he has given it since in a good many cases of pyrexia due to various causes; among others, a case of rheumatic fever with advanced mitral disease, in which it controlled the symptoms admirably without apparently causing any considerable depression. In two cases of severe pneumonia occurring in children he has used the drug, and it seemed to have a beneficial effect, both children making remarkably good and speedy recoveries. Such results, he says, encourage him to make further trials with the drug in cases of pyrexia in which either phenacetin or the salicylic group has been found useful, but especially the latter, as its use seems to be attended with a minimum of the bad effects sometimes seen under the administration of those drugs.

**Indian Hemp.**—In the *British Medical Journal* for February 9th Mr. R. Cowan Lees, of Glasgow, has an article on this subject in which he remarks that it has always been difficult to understand why the resin of this plant should alone be recognized in the *British Pharmacopoeia*, more especially when, in works on the physiological action of this drug, it is stated that in India several preparations are employed by the natives to produce its stimulating and exhilarating effects, among which watery infusions are specially mentioned.

During the author's visit to India some years ago he noticed that several modes of using the herb were employed by the natives. So far as he could observe, watery infusions were commonly used, but whether in combination with other substances or not he does not know. This fact, however, led him to try what benefits might be derived from the use of a preparation of the plant not depending for its virtues on the resin alone.

The men who first obtained the resin in a state of comparative purity state that it is a "brown amorphous solid, burning with a bright-white flame, and leaving no ash; it is powerful in its action when taken internally, and two thirds of a grain act as an active narcotic, while one grain produces complete intoxication."

When the extract is kept for some time it becomes hard and brittle and less potent in its action, a circumstance which goes a long way, says the author, to prove that such a condition is the result of loss of volatile oil from the resin, and pharmacists are advised not to employ for medicinal use which has become old. Bentley and Trimen state that "both Hindus and Mohammedans use this herb in smoking, or by simple infusion in water." Gunjah, the guava of the London market, has but a faint taste, with a peculiar but not unpleasant narcotic odor. These properties depend in a great measure on the volatile oil and on the resin. The latter is considered by some as the more important constituent of the plant. Dr. Personne, says Mr. Lees, regards the volatile oil as the sole active principle, and he states that "when the volatile oil is inhaled a distinct sensation of shuddering, with motor excitement, followed by prostration and syncope, is experienced." Again, Dr. Preuschersky found a volatile alkaloid—very plentiful in the flowering tops—which he considers somewhat similar in its action to nicotine.

The author, feeling satisfied that water was capable of dissolving at least a portion of this volatile oil, had a strong aqueous extract prepared from the flowering tops of the female plant, of the usual strength of liquid extracts, and from its use he has obtained good and satisfactory results. It possesses the anodyne and soporific action generally ascribed to the resinous extract, although in a modified degree. It has the characteristic odor of the hemp, and has a beautiful deep amber color; it is miscible with water, and therefore there is no difficulty in combining it with other liquids, and it presents no unseemly appearance repellant to a patient.

Liquor cannabis indicum, says the author, in all his experience gives all the beneficial effects without the drawbacks of the tincture, which are sometimes met with even when using a medium dose of it. It does not seem to interfere with the secretion of mucus from the bronchial glands, which renders it superior to opium in certain cases, while in pulmonary affections generally it acts most favorably as a soporific and anodyne.
Mr. Lees states that his greatest experience with the drug has been in the treatment of phthisis pulmonalis, and in these cases he says he can not speak too highly of it, for not only does it most perceptibly relieve the cough, but it aids the patient by its stimulating and exhilarating qualities, supplying a remedial agent in a manner which, in his opinion, no other drug can so beneficially do. In indigestion with constipation, and also in many children's affections, especially where nervous symptoms are present, it has also done good service. The author does not suppose for one moment that it will displace opium where severe pain is a prominent symptom, but he feels sure that in many cases it may be substituted for opium with great advantage.

The dose which he commonly employs is half a fluidrachm for an adult, but it may be increased to a drachm in many cases; while for children doses according to the age may be adopted, although, he says, he has noticed that children are somewhat less susceptible to it than adults.

**A Chemical Antidote for Chloral Poisoning.**—The Glasgow Medical Journal for February publishes an article on this subject by Dr. John Dougall, of Glasgow. When chloral was first used, says the author, its hypnotic action was thought to be solely due to the generation of chloroform from it by the alkalies of the blood; its effects on the body generally were, and indeed still are, held as almost identical with those produced by chloroform. This view, however, he says, has been disputed on the grounds that the quantity of chloroform which a full dose of chloral is capable of producing is quite inadequate to cause the hypnosis and anesthesia that have been observed, also that the greater part of the chloral is exhaled from the lungs unchanged, and that small quantities of it may be found in the urine, but no chloroform. Whatever facts or theories, however, says Dr. Dougall, there may be regarding the manner of the hypnotic and anesthetic action of chloral, there can be no doubt about its chemical composition and affinities, and, in particular, that it is almost at once decomposed, at and above 60° F., outside of the body in an alcoholic solution of potash into formate of potassium and chloroform, and, as the author has proved by trial, somewhat less quickly in an aqueous solution of potash.

Assuming, he says, that a person has taken a poisonous dose of chloral, say eighty grains, and that there could with safety be given, as a chemical antidote, twenty-seven grains of potash, this amount being the quantity by weight in the formula required to decompose eighty grains of chloral—in such a case, says the author, there are strong a priori grounds for assuming that in about fifteen minutes the chloral in the system would be entirely changed into formate of potassium and chloroform or, at least, that so much of it would be decomposed that the residue would be harmless. But would not the potash, he asks, or the amount of its formate, or of the chloroform thus produced, be as lethal as the chloral? Undoubtedly twenty-seven grains of potash swallowed at once, even much diluted, would cause serious symptoms. But if even half that quantity was given in divided doses—say seven grains every hour—in warm milk, gruel, or barley-water, it seems very probable that by this means no serious irritation of the gastro-intestinal tract would be the result, and that in a short time so much of the chloral would be decomposed as to render the rest at least non-lethal.

The liquor potassae of the British Pharmacopoeia, says Dr. Dougall, contains about a grain of potash in sixteen minims, and the maximum dose stated is sixty minims. Hence, he says, to give seven grains of potash is equal to giving a hundred and twelve minims of liquor potassae. He thinks it may be assumed that this quantity, highly diluted, might be given without fear of causing unfavorable symptoms. By this means twenty grains of the chloral would soon be decomposed, thereby neutralizing its lethal power to a certain degree, if the potash is given before the patient is too far gone to be afforded relief by this means; then, if in an hour after a similar dose of potash is given in the same way, this would reduce the chloral in the system to forty grains, a quantity quite within the bounds of safety for an adult, provided there is no heart trouble.

Dr. Dougall says that he has proved by experiment what has been stated by others—namely, that the carbonates and bicarbonates of potassium and of sodium also decompose chloral; but their action, particularly that of the bicarbonates, is very slow, and, besides, a much larger quantity than of potash is required, also a heat much above that of the body. With regard to the action of formate of potassium, it merely causes a peculiar eruption of the skin, which soon disappears when the use of the drug is stopped. This eruption is well known to habitual chloral-takers, and seems to prove that chloral is decomposed in the blood as stated.

With regard to the probable effects of the chloroform which would be generated by the decomposition of forty grains of chloral, the author finds that this quantity of chloral requires 13.5 grains of potash for its decomposition, which results in the production of 28.5 grains of chloroform, equal to 21.5 minims. As much larger amounts of chloroform (even half an ounce to four ounces) have been swallowed and recovered, it has followed, and as it is likely that the greater part of that which is generated in the blood by the decomposition of the chloral is exhaled as fast as it is produced, Dr. Dougall thinks that nothing serious need be feared on this point.

**The American Inspection of Emigrants in France.**—The Progrès médical for January 19th says that several newspapers have published a dispatch from Washington, according to which the French and German governments have prote-teed against the presence, in certain French and German ports, of the American medical inspectors who control the embarking of emigrants for America. The American government is said to have replied that the diplomats and consuls were not, from the nature of their functions, competent to exercise the control with which these inspectors were charged—a useful function, says the Progrès médical, for it saves the American government from being obliged to return to France or to Germany those emigrants who do not fulfill the requirements for admission into the United States. The matter, moreover, has terminated in the most satisfactory manner, for the American medical officers have obtained from the French government all the facilities they could desire for the accomplishment of their mission.

**The Treatment of Frostbites.**—The Lyon médical for January 27th publishes the following suggestions from M. Bessier and M. Brocq: For frost-bitten hands, bathe the hands in a decoction of walnut leaves; dry them and rub them with strong timetare of camphor, then dust them with the following powder: Bismuth salicylate, 150 grains; starch, two ounces and a half. For allaying the itching at night a mixture of a grain and a half each of rose water and tamin and an ounce and a half of glycerin should be rubbed on the hands, and this is to be followed by the use of the powder. If the hands are ulcerated, they should be wrapped in walnut leaves softened in hot water.

Another remedy the efficacy of which has often been witnessed is three ounces of fir balsam and fifteen drops of hydrochloric acid. This should be applied to the affected parts twice a day.
Original Communications.

SPONTANEOUS GANGRENE FOLLOWING TYPHOID FEVER.*

By L. HARRISON METTLER, A.M., M.D.,

CHICAGO.

Literature contains many isolated reports of cases of dry and moist gangrene following typhoid fever, but the systematic study of this occasional and sometimes fatal sequel is still wanting. The subject was first broached by Bourgeois d'Etampes, in 1857, before La Société médicale des hôpitaux de Paris. Dr. Charcellay, of the Hospital of Tours, had a case in 1843 in which the whole left side of the face underwent mortification. Patry many years ago referred to gangrene as a sequel of typhoid fever and associated it with an arteritis—a view in which Hayem could not concur. For so important a complication, it is surprising that so little mention has been made of it in the standard authorities. Reynolds, Bartholow, and Wilson do not allude to it at all. Flint states that he never saw a case, while Keen is sponsor for the assertion that Trouseau never saw a case. I find, however, that Trouseau referred to a case reported by Dr. Boudeau wherein gangrene of the right foot took place in a child ten years of age. Unlike either Patry or Hayem, he attributed the accompanying arteritis to the clot acting as a foreign body upon the walls of the blood-vessels. Murchison and Hutchinson each devote but a brief paragraph to its consideration. Broadbent and Liebermeister say nothing about it. Fagge merely mentions the possibility of a thrombus of the femoral vein with an attendant liability to pulmonary embolism. Strümpell makes no reference whatever to gangrene following enteric fever. Osler assigns a short and incomplete paragraph to it. Most of the works on surgery that I have consulted simply mention the possibility of its occurrence. The fullest treatment of the subject that I have been able to discover is W. W. Keen's Toner Lecture, which, however, is dated 1876.

And yet this is not such an uncommon sequel of typhoid fever as all this reticence on the part of the authorities would lead one to imagine. I have seen two well-marked cases—one in a child ten years of age, in which amputation of the right leg had to be performed; the other in a woman, seventy years of age, in which both femoral vein and artery were obstructed, ultimately causing death. Both cases have already been placed upon record.† Out of one hundred and thirteen cases of gangrene following fever, collected by Dr. Keen, forty-three followed typhoid fever. Barchoud‡ has tabulated some twenty cases of arterial obstruction following typhoid fever, and of these eight proved fatal. During an epidemic of typhus and typhoid in Finland in 1865, Estlander saw thirty-four cases, all of which, however, followed typhus fever except one. Most of the writers who have considered the subject at all do not report more than one or two cases that have come under their observation. As the result of a rapid glance through the more recent literature, I have made notes of cases reported by Sallès, Hanquet, Wedewsky, Gosse, Drewitt, Fränkel, Donkin, Newbolt, Cushing, Lucas-Championnière, Keim, Long, Koeln, Chew, Laporte, and Grancher.

Among the predisposing causes of this complication of typhoid fever are lowered body vitality, mental depression, and an unsanitary mode of life. It is more frequent, therefore, in epidemics and in times of disaster. Most of the cases occur prior to the middle period of life. In Keen's collected cases the ages varied from fifteen to twenty-five years. In my own two cases they were ten and seventy years of age. In those I have collected from the later literature they were from eleven to thirty-two years. As typhoid fever itself is a disease of the early half of life its complications would necessarily correspond. Both cases observed by me were in females. Of eighty-one cases of Keen's list, fifty-six were in males, twenty-five in females. Of nine patients in my list whose sex was reported, six were men, three were women. It is therefore predominant in the male sex. In both cases reported by me it occurred in the lower half of the body; in the calf of the right leg of the girl, in the right leg and part of the thigh of the woman. Out of ten of my collected cases the obstruction was discovered in the lower extremities, usually the left, in six instances, once in the left cheek, once in the mesentery vessels, once in the left carotid. When it occurs in the cerebral arteries, the complication is usually classified among the neurotic, because of the hemiplegia that results. In one hundred and twenty-six of Keen's cases it took place seventy-seven times in the extremities, chiefly the lower, and in twenty-two cases in the peripheral districts of the vaso-motor system, such as the ears, nose, and genitals. This clearly demonstrates that it is a complication of the peripheral vascular apparatus.

This peripheral distribution of the trouble led the earlier investigators to attribute it entirely to the weakened heart action and slackened blood current. Even to-day many lay great stress upon this mechanical cause. Keen is so convinced of the tremendous importance of this that he declares it "will more readily and rationally explain the causation of the gangrene," even in those rare cases where there is no clot, "than any specific action of the indefinite though undoubtedly poison of the fever." A moment's thought, however, ought to convince one of the inadequacy of such a simple explanation. Arterial obstruction with resulting gangrene is far too rare a complication to be attributed solely to a condition which obtains with almost invariable constancy in enteric fever. Except in the very mildest cases the typhoid heart always manifests a dangerous weakness until far into convalescence, and yet vascular obstruction occurs quite infrequently in the disease. We must not be misled by the fact that this complication usually appears in the third week of the fever, and not infrequently when convalescence has become well established.

* Read before the Chicago Medical Society, January 21, 1895.
† Philadelphia Medical Times, Feb. 19, 1887.
for there is still something more than mere blood stasis needed to account for its wide distribution, comparative infrequency, and insidious onset. In Wedekind's case a symmetrical gangrene appeared two years after the attack of fever and was attributed "to the toxic action of the products of the activity of the typhoid bacillus."

Pathologists at the present time are generally agreed that the obstruction of an artery by a clot is in the vast majority of cases at least the cause of the gangrene, but as to the cause of the clot there is still a diversity of opinion. An endocarditis distributing emboli which finally become fastened in some narrowed portion of the arterial system, and so become the nuclei of the future thrombi, has been designated as one cause. If this were the case we should expect the gangrene to appear in other parts of the body quite as frequently as in the lower extremities; but, as a matter of fact, out of a hundred and twenty-six localities affected in the cases cited by Dr. Keen, seventy-seven were in the extremities, and seventy-two of these in the legs. Furthermore, endocarditis, according to Wilson, is a very rare complication of typhoid fever. In neither of the two cases reported by me could the slightest indications of it be detected.

Another explanation of the appearance of the clot has been the combined effect of (a) "the altered blood"; (b) "the weakened heart"; and (c) "the mechanical difficulties in carrying on the circulation, especially in distant parts." While these may undoubtedly be powerful factors in assisting in its formation, it does not seem to me, when we study the history of the cases thus far reported, that any one of these conditions, or even all three combined, are immediately the cause of the clot. The same conditions are present in other severe forms of fever, such as pyemia, puerperal fever, diphtheria, and pneumonia, and yet mortification of extensive areas due to an arterial obstruction is never so imminent as in typhoid fever. Moreover, in typhoid itself these conditions are very constant and well marked, but the gangrene, as Dr. Keen truly says, "is happily a rare complication." Let us consider for a moment each of these conditions, whose combined effect is said to produce the clot. Barić, writing in 1884 for the Revue de médecine, states that the spontaneous occlusion of an artery by what Virchow calls "marasmic clots," or clots due simply to a certain condition of the blood, "is almost impossible" in typhoid fever, because of the peculiar kind of change in the blood of that fever, represented by a "diminution of the hemoglobin, of the red corpuscles, and plasma." And again, as Green says, "to whatever cause it may be due, an increased tendency of the blood to coagulate is probably never more than a predisposing cause of thrombosis." Thus the "altered condition of the blood," aside from the fact of its bearing a specific poison of a high degree of virulence, can not be accepted as any more than a predisposing cause of thrombosis, especially if the endothelium remains intact. Secondly, as to the "weakened heart," it needs but a moment's reflection to understand that this also is nothing but a predisposing cause in producing a retardation of the blood current. A weakened heart is characteristic of many other diseases in which gangrene is scarcely ever known to occur. Thirdly, as to the "mechanical difficulties in carrying on the circulation." This and the weakened heart condition act much in the same way to produce a stagnation of the current, a distended state of the arteries, and an impaired nutrition of the arterial walls, through a consequent abnormal condition of the vasa vasorum, the whole terminating in an arteritis of greater or less degree. But how are we to explain the tendency to gangrene that so generally accompanies typhoid fever—a fact upon which M. Behier laid marked stress so long ago as 1857—and its singular absence in other diseases in which arteritis of the same sort ought frequently to obtain, seeing that in them this condition of the heart and circulation is almost as common as in typhoid fever?

The more I have studied this question, the more am I convinced that the production of arterial thrombosis and subsequent gangrene in typhoid fever is due in by far the greater majority of cases to an endarteritis assisted by various mechanical factors. The immediate cause of this endarteritis is in all probability the fever poison in the blood in a condition of extreme virulence. It is the result of an intense toxemia. That this is the state of the blood, or that this is its effect upon the inner lining of the arteries, is established by the "almost constant muscular degeneration" which is so peculiar to typhoid, and which has been attributed to an inflammatory obstruction of the arteries supplying the muscular tissues. In this way do Hayem and Martin explain the myocarditis and subsequent softening of the heart muscle. Giraudou attributes the degeneration of the general muscular system to an infectious myositis and that of the various viscera to the hemorrhagic infarctions all produced by the same cause—viz., a primitive obliterating arteritis induced by a highly poisonous condition of the blood. Arteritis has been attributed to the poisoned blood state invari (Brouardel), diphtheria and marsh miasm (Lancecoves, Verneuil), tuberculosis (Lancecaves), syphilis, and rheumatism. Inflammation of the arteries from this cause is not, therefore, an uncommon affair. Of a hundred and thirteen cases collected by Keen, however, it is seldom stated that the arterial walls were diseased. This may easily be accounted for by the comparatively incomplete autopsies that were often made in these cases. So many of these cases occur in private practice, and they are, moreover, so rare, that unfortunately post-mortem examinations are hard to obtain. In neither of my cases was an autopsy permitted, though the symptoms in the case of the girl pointed obscurely to an endarteritis of the obstructed vessel. In Fall's case it is expressly stated that there was an "obliterating arteritis," and in the more numerous cases of venous obstruction a phlebitis appears to have been a manifest cause. The signs of the arteritis, when it occurs, make their appearance first about the latter part of the third week, or the beginning of convalescence. The pain along the course of the vessel may be of a sharp, stinging character, or dull and aching. One patient likened it to the "stretching or tearing of the nerves of the limb." Movement, external pressure, or simply the erect posture increases it. There is occasionally violent throbbing of the blood-vessel, not infre-

quently felt in parts of the body situated at a considerable distance from the inflamed artery. Finally, the pulse beat becomes hard and wiry. As the vessel becomes less and less permeable, and the blood supply of the contiguous tissues diminished, there will be noticed a slight lowering of the local temperature, oftentimes as much as several tenths of a degree. The skin assumes a bluish or violaceous hue, while its sensibility is considerably enhanced. All symptoms of arteritis, and especially endarteritis, are exceedingly obscure, pain being the most reliable, and this having to be carefully distinguished from the pain of neuralgia, phlebitis, and lymphangitis. It is from these obscure symptoms rather than from more exact autopsies that an obliterative arteritis has been given the credit of the formation of the clot. Among those who support the view of a general primitive arteritis occurring in typhoid fever, based upon the few autopsies made by themselves, may be mentioned Gigon, Hayem, Patry, Larroque, Behier, Bourdeau, Mercier, Mas- scell, and others. In view of this, as well as of the fact that "abnormality or removal of the endothelium is the essential condition" (Green) to the formation of the clot, it is difficult to harmonize the presence of the clot with the reported healthy condition of the arteries in so large a proportion of Dr. Keen's cases. I think we may safely conclude that the cause of gangrene following typhoid fever is an obliterative arteritis lighted up by a virulent toxaemia, and that its appearance and frequency are determined by the vitality of the patient's tissues, the degree of virulence of the blood-poison, and certain minor mechanical factors.

The prognosis depends upon so many attendant circumstances that it is difficult to form any decided conclusions. It is less favorable than gangrene under other conditions by reason of the exhausted state of the patient produced by the attack of fever. Exhaustion practically destroyed both of my patients, though the little girl lived six weeks after the amputation. Of Barchoud's twenty cases, eight proved fatal. Barker and Cheyne have recorded a case in which death occurred two hours and a half after gangrene had begun in the nose. In a few cases of obstruction a collateral circulation has been established, and in a still smaller number there has been a restoration of the lumen of the obstructed vessel. It is more common, however, for a line of demarcation to appear after the lapse of a few weeks and Nature to relieve the patient of the mortified tissues. I need say nothing in regard to the prophylaxis and treatment of this complication of typhoid fever, as they differ in no respect from the treatment of gangrene under other circumstances.

THERAPEUTIC EFFECTS OF CARBONIC ACID

IN DYSENTERY, IN THE VOMITING OF PREGNANCY, IN WHOOPING-COUGH, IN PROSTATITIS, AND IN IMPOTENCE

By A. ROSE, M.D.

I published in a paper entitled Carbonic-acid Gas as a Local Application to Chronically Infamed Mucous Surfaces. In this article I described the method of von Ziemssen of inflating the large bowel by carbonic acid for the purpose of diagnosis and the reduction of abnormal positions, of strangulations, intussusceptions, and twistings of the colon. I spoke of the physiological effects of carbonic acid upon and its absorption by the skin. I came to employ carbonic acid in ulcers of the rectum, reasoning at that time that carbonic acid was a disinfectant and an antiseptic. I had been aware that Demarquay had made use of carbonic-acid gas in the treatment of chronic ulcers of the leg, that Johnson had reported excellent results from the application of carbonic-acid gas to diphtheritic ulcers, that Broca and others had applied carbonic acid in neuralgia of the bladder; that, in general, carbonic acid had been successfully employed in such forms of neuralgia as were amenable to local treatment, as, for instance, neuralgia of the uterus; that it was highly recommended in the treatment of amenorrhea and dysmenorrhea; that ulcers of the cervix uteri, upon application of a carbonic-acid-gas douche, ceased to be painful and healed promptly. It was also known to me that Scanzoni and Simpson had introduced the local application of carbonic acid into gynæological practice.

Thus the beneficial effects of carbonic acid on ulcerating surfaces in general and on ulcers of the neck of the womb in particular suggested to my mind the idea of applying carbonic acid to the ulcerated mucous membrane of the rectum. The first case was one of obstinate dysentery:

Mary R., nineteen years and a half old; domestic. Fairly developed. Had been enjoying tolerably good health. On September 2, 1883, she was taken sick with fever, diarrhea with tenesmus, and vomiting. The day following the stools contained matter and blood. At that period we did not yet distinguish amebic, diphtheritic, and catarrhal dysentery. I saw her first on September 5th. I poured into the rectum both large and small quantities of warm water at varying intervals, while the patient occupied a recumbent position. I did this as I had often found it successful in relieving tenesmus. None of the drugs employed, such as calomel with opium, castor oil, tannin, bismuth, and lead acetate, had any marked or lasting effect. The patient remained feverish, and suffered greatly almost every night from frequent tenesmus, and continued to discharge blood and matter. The little relief she obtained was more from applications of ice to the abdomen than from any other means employed. On September 19th, after having anesthetized the patient, I made a thorough examination of the rectum. The mucous membrane, as far as it presented itself to view, was swollen, of a dark-red color, and studded with deep ulcers thickly covered with matter. After having cleansed the rectum with water, I cauterized all the ulcers with nitric acid. The first night after this procedure the patient slept well, did not suffer from tenesmus, and felt better every way; the night following, however, she was as bad as ever.

Almost from the commencement of her sickness the patient had been coughing; physical examination showed slight dullness on percussion on the right side, below the axilla; between the third and fifth ribs, and, corresponding with this area, crackling sounds on inspiration. The patient being very much reduced by constant fever, restlessness, and pain, and presenting this probably metastatic affection of the lung (if the case happened at present, we should look for amebae), her case appeared indeed a desperate one.

In the forenoon of September 27th I inflated the rectum
with carbonic-acid gas, and this one application, which caused no discomfort or tenesmus, was at once followed by a change for the better. There was no fever on that evening, and very little tenesmus during the night; she slept well and improved, so to say, from hour to hour in every way. There was some matter and blood discharged, but only during the night following the first application; the next morning she had a natural evacuation from the bowels without either matter or blood, and never again discharged either. Tenesmus ceased gradually during the following nights. There was no more straining after October 1st. For nearly five days the bowels moved as often as five or six times daily, very little at a time, passages in the shape of small, hard balls; and as long as this was the case, I had the carbonic-acid douche applied three times a day. The applications, according to her statement, produce an agreeable sensation, and she asks for them. The patient then made a speedy recovery. The bowels since October 4th moved regularly and naturally once a day. There is still slight dullness on percussion on the right side and diminished breathing, but there are no more crackling sounds, and the cough has almost ceased.

I shall not occupy space with the report of other cases. Suffice it to say that whenever during the last eleven years I have applied the carbonic-acid douche to inflate the rectum in cases of dysentery, I have had the same gratifying result as I had in this first case.

Carbonic acid, when introduced into the large intestine, as a rule, does not pass the ileo-cecal valve. Experiments on the cadaver have shown that inflation of the intestine has a certain limit corresponding with the limit of inflation of the intestine of the living. Neither in the living nor in the dead body can gas or liquid be forced through the valvula Bauhini while the abdominal walls are intact, and even with the abdominal walls wide open the passage of gas or liquid can only be accomplished when the injection is made quite close to the valve; when the injection is made from the anus it seems the ileum can not be inflated, or only imperfectly so, even when the abdominal walls are wide apart. It is not so much the valve itself which prevents regurgitation, but there are certain other mechanisms which secure a firm closure: probably the physical and physiological condition of the abdominal muscles, the action of the diaphragm, the difference between the lumina of the intestine at the one and the other side of the valve, and many other circumstances and arrangements. Altogether, the considerable power of resistance of the ileocecal valve against regurgitation from the colon into the ileum is the effect of quite a number of factors. According to von Ziemssen’s observation, it seemed as if this power of resistance of the valvula Bauhini was somewhat lessened during deep chloroform narcosis, and the small intestine then became measurably inflated. Nothnagel reports a case of enterostenosis in which the patient’s death was with certainty to be expected. Shortly before exitus a moderate amount, three hundred and fifty grammes, of a ten-per-cent. chloride-of-sodium solution, colored with carmin, was poured into the rectum under moderate pressure. Post mortem, the red carmin coloration was found as far up as forty-five centimetres above the valvula Bauhini. In two experiments made by Danseh* on patients the air forced in passed into the smaller intestine, although but a small amount of air was employed. In both these cases there appeared to be no resistance at all on the part of the valve. One was a case of old hemiplegia with symptoms of intestinal paralysis; the other was a patient who formerly had suffered from lead palsy. However, cases in which inflation made from the rectum extends beyond the valve are exceedingly rare.

Carl Fränkel† made experiments to study the effect of carbonic acid upon micro-organisms and found that certain bacteria could live and thrive almost as well in pure carbonic acid as in atmospheric air, that others could develop only imperfectly or slowly in CO₂ and that a third class did not grow at all, except when the cultures were exposed to a breeding temperature; the majority of the others, especially the saprophytes, did not thrive in carbonic acid, although they did not perish therein; they would develop again when brought into atmospheric air. Some bacteria, among them those of anthrax and cholera, are destroyed by CO₂, but not those of typhus abdominalis. Carbonic acid can not be considered as an antiferment. Proteus vulgaris is affected by it, however. Whenever carbonic acid acts as a germicide it will lose its effect when it becomes admixed with even small proportions of atmospheric air. Kolbe had said that beef kept in CO₂ did not putrefy for two to three weeks, but Steinmetz had found that there was simply no odor of putrefaction; the germs had actually multiplied. Dryness and CO₂ may prevent the development of the odor of putrefaction, but not the development of bacteria.

Early in the year 1884 I was called to Brooklyn as consulting physician in a case of incessant vomiting in pregnancy. All the usual remedies had been employed in vain. I for the first time suggested the introduction of carbonic-acid gas into the vagina, and exhibited my simple apparatus, which I shall describe presently, to accomplish this. My idea was to make use of the anesthetic effect of the gas on the womb, especially on the os. I assumed that the vomiting in this case might be a reflex action, originating in neurosis of the womb. For some reason or another my suggestion was not accepted.

Later on, by experimenting with carbonic-acid gas in some other direction, I found that inflation of the rectum with CO₂ had a more decided stimulating effect on the sexual organs than its application to the organs themselves; probably because the rectum offers better facilities for absorption.

Dr. Adrian Schäcking, of Pyrmont, Germany, arrived at the same conclusions, independently of me, in 1885. He published in the Centralblatt für Gynäkologie an article entitled Zur Therapie des Vomitus Gravidarum, in which he describes a case of incessant vomiting of pregnancy in which, other measures having failed, he irrigated the rectum with the carbonated water from the Pyrmont Spring.

† Zeitschr. f. Hygiene, Bd. v, II. 2.
This water is highly charged with the gas. After the first application of this water the vomiting ceased. In the same paper he recounts a case of incessant vomiting in a girl with an ovarian tumor, in which, as in the preceding one, the vomiting was controlled by irrigation of the rectum with carbonic-acid water.

I confined myself to inflation of the rectum with gas, and never applied the gaseous water in cases of vomiting in pregnancy. The results were invariably gratifying. I have not met with another case of so-called incessant vomiting. Perhaps by my applying the carbonic acid early, graver symptoms were prevented in one or the other of those I attended.

In certain forms of intestinal obstruction it has been recommended to make use of an ordinary siphon bottle containing carbonic acid water, to attach a rubber tube with a nozzle to the mouth of the bottle, and turn the latter upside down, if we wish to introduce the dry gas. This mode of procedure can not be employed in case of pregnancy. No matter how gently we press on the knob to discharge the gas, the effect, on account of the high pressure under which the gas is in the bottle, is unpleasant, perhaps dangerous. A severe shock is felt in the abdominal organs.

Since the year 1887 Bergeon has been using CO₂ in whooping cough. He injects it immediately after the attack, under the condition that three hours have elapsed since the last meal, into the rectum. The child is allowed to eat at once after the inflation, as the digestion is not interfered with. If a fresh coughing spell sets in, the inflation is to be repeated as soon as in four hours after the one previously made. In very obstinate cases he inflate also during the night. According to Bergeon, even the severest forms require only a week of treatment. Bergeon has published much and spoken much on this subject in medical societies, but has not made proselytes. Recently it happened at a dinner party of medical men that he was sitting next to Professor Girod, who had been suffering for three months from whooping-cough and had tried in vain a number of remedies. Bergeon interested Girod in his method. Girod tried it with excellent result on himself and also on his children, who were at the time similarly afflicted.

I forget when and where I first read of the employment of carbonic acid inflation in whooping cough. It is since May, 1894, that I have been employing this method of treatment, and more recently I have had opportunity to order it in quite a number of cases among the patients whom I am attending for the St. Luke's Society of Grace Parish. In all cases except a few the reports I have received have been that the application of the gas had had an unmistakably good effect. Relief was observed in the very first days and the patients were entirely cured within from eight days to two weeks. As a rule, the children coughed less frequently after the first application; after four or five days' treatment they ceased coughing during the night; during the day they would cough only after they had been running or had had similar exercise. I attended a family in which the mother and two children were suffering from pertussis while they sojourned at a fashionable seashore hotel. In this family also the mother's sister, who remained in New York and only occasionally visited her sister and the children at the seashore, became affected and was subjected to the carbonic-acid treatment as soon as I had made the diagnosis. In all these cases the result was most gratifying. I do not lay down any rules, as Bergeon does, as to the frequency and the time of application. I only direct that the inflation be made at least two or three times a day. I have found that the result is the better and the more prompt the oftener the inflations.

I have to confess that I have learned that in two out of about forty cases of children treated for St. Luke's Association the mothers had reported that there was no improvement. Noteworthy is it that in both these instances the treatment with CO₂ met with success in other children of the same family.

CO₂ from whatever part of the body it may be absorbed, enters through the venous system into the lungs, and from there it is exhaled. Physiological observations have shown that by the acts of inspiration and expiration the larger upper air-passages are only ventilated, while the essential portion of the respiratory act, the exchange of CO₂ and O by means of diffusion, is executed in the alveolar domain of the lung, and that therein the phases of respirations are almost un concerned. Thus we find a continuous moving of CO₂ upward and of O in the opposite direction. A necessary consequence of these conditions is that the air in the respiratory tract in the direction from the mouth toward the alveoli has gradually less and less oxygen, but more and more carbonic acid. A. Ephraim * assumes that by the increased amount of CO₂ passing from the blood into the alveoli an increased exchange and diffusion of the two gases is brought about, and corresponding with the increased exhalation of CO₂ there is, according to the laws of diffusion, also an increased influx of O toward the alveoli. Ephraim is also of the opinion that the more oxygen there is absorbed by the blood the more carbonic acid is given off; that between the blood and the air in the alveolar cells there is likewise a greater activity of diffusion under these conditions.

As the best method of introducing CO₂ into the system Ephraim recommends its administration by the rectum. He reports favorable results in cases of chlorosis, phthisis pulmonalis, bronchitis, asthma. He calls it a method to improve pulmonary ventilation.

According to this theory we can readily explain why the inhalation of pure oxygen or the much-advertised "compound oxygen" is of comparatively little value.

I have been treating prostatitis by means of a rectal cone. This is a metallic cylinder after the principle of a cooling or, as the case may be, warming sound, through which I pass ice water in acute cases to relieve the well-known exacerbating pains of acute prostatitis, and warm water in the chronic stage of this affection to stimulate

circulation. Recently I have substituted inflation of the rectum with carbonic acid, both in the acute and in the chronic stage of prostatitis, and find that it has a superior effect as an anesthetic as well as a means to accelerate circulation.

In the healthy state or in disease the inflation of the rectum with carbonic acid brings on a rather pleasant sensation of warmth, indicating increased circulation of the parts nearest the rectum. Wertheim recommends the application of carbonic acid gas to the male sexual organs to relieve impotence. I have not been able to find a description of his mode of application. An irregular practitioner of this city, about twelve years ago, had the idea of imitating Demarquay's method of incising an ulcerated leg in a rubber bag to be inflated with CO₂; he constructed a rubber bag to incise the penis and the scrotum for the purpose of applying CO₂ to these parts.

I have had only a limited experience, but it appears to me that inflation of the rectum with CO₂ is the best remedy to relieve impotence. The beneficial effect in those cases which I have been attending has been a prompt one. I am positive the carbonic acid thus applied acts as an excellent stimulant.

The apparatus which I employ is very simple: it consists of a bottle, holding a pint or more, with a wide mouth and a rubber stopper, the latter perforated so as to admit a glass tube, which at the external end is connected with a rubber tube, at the farther extremity of which is attached a nozzle to be introduced into the rectum. I fill the bottle one third full with water. The glass tube in the bottle is to reach as far down as one or two inches above the level of the water. Into the water I first put about six drachms of bicarbonate of sodium, and then, when everything is ready to administer the inflation, I add half an ounce of large crystals of tartaric acid (if pulverized acid is used, the development of the gas goes on too rapidly). The bottle is now closed quickly; the carbonic acid rises through the tube and inflates the rectum. Any position—Sims's, for instance—may be selected for the introduction of the gas. As soon as meteorism or a considerable sensation of tension in the rectum is perceived the nozzle may be withdrawn, or the patient may, while the nozzle remains in situ, free himself from as much gas as he can not well retain in the rectum. The inflation is then repeated as many times as is required until all the gas in the bottle is exhausted.

215 Second Avenue.

THREE CASES OF BROWN-SÉQUARD PARALYSIS, WITH REMARKS ON THE SENSORY TRACT IN THE HUMAN SPINAL CORD.*

By PAUL BAILEY, M.D.,
ASSISTANT IN NEUROLOGY, VANDELBINT CLINIC;
ASSISTANT IN PATHOLOGY, COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK;
ATTENDING PHYSICIAN, ALMSHOUSE AND WORKHOUSE HOSPITALS.

Of the three cases here detailed, one, which I am able to report through the courtesy of Dr. Fisher, I have seen constantly in the neurological division of the Almshouse Hospital on Blackwell's Island. The two others have been at the Vanderbilt Clinic in the course of the past two years. Dr. Starr has kindly permitted me to look them up and examine them:

Case I. Right.—Diminution of tactile sensibility; analgesia; thermo-anesthesia; all reflexes present; no clonus; no loss of muscular sense.

Left.—Stab wound of neck; myositis; cilio-spiral reflex absent; paralysy, with contractures, of arm and leg; wrist, elbow, and knee joints exaggerated; clonus; cremaster reflex diminished; abdominal reflex absent; no loss of muscular sense.

The patient, a Norwegian, aged forty-seven years, first found his way into the Almshouse Hospital last October for a malarial fever, which yielded quickly to quinine. His nervous condition being recognized, he was transferred to the Hospital for Incurables. I wish to take this opportunity to thank Dr. Wimber, the house neurologist, for his efficient assistance in the report of the case. The history which he tells is as follows: That soon after his arrival in this country, twelve years ago, he was stabbed in the back of the neck close to the skull on the left side. His history, both personal and that of his antecedents, previous to this time is of no medical interest. He was unconscious for three hours after receipt of this injury, and was removed to Chambers Street Hospital. On regaining consciousness he found himself hemiplegic on the left side. The fact that he was hemi-anesthetic on the right side was not noticed until some time later. His head hung limp upon his right shoulder, and for five weeks he was in bed with his head in supports. At the end of that time the power began to return to the leg, and still later to the arm. Complete return of muscular strength has not occurred in either, and, though the leg is better than the arm, both are stiff. Sensations in these limbs were normal. On the right side tactile sensibility was but slightly affected, while sensation for pain and temperature was so much impaired that ordinary cuts, bruises, etc., caused no pain unless very severe. He could hold a piece of ice in his right hand indefinitely, and could not distinguish between hot and cold water. A bedsore developed over the right buttock, and there was a temporary paralysis of the bowels. All the improvement which occurred was complete in eight months. Since then his condition has been what it is at present. He has been subject to ulcérations on the right leg, and had incontinence of urine for one year after the injury. After that time the urine passed involuntarily if the patient were on his left side; now, if asleep on his left side, it passes involuntarily. He is a man of medium frame and fairly well nourished. On the right leg are numerous scars, results of local suppuration which has occurred since the injury. Examination of the vegetative organs is negative; mentality is unimpaired, and he is a man of

* Read before the New York Neurological Society, January 8, 1895.
There is fair intelligence. On the left side of the upper part of the neck, in front of the anterior border of the trapezii and about an inch from the median line, is a scar which is the result of a punctured wound. On palpation over this scar the finger comes upon the posterior arches of the atlas and axis. There is no pain on pressure in this region. The head is deviated to the right to a slight degree. All the cranial nerves are intact. There is slight hypermetropia, and the left pupil is somewhat smaller than the right. There is also a slight internal squint of the right eye, dating from childhood. While there is general weakness of the arm and leg on the left side, this is most marked in the muscles of the shoulder and in all the extensors. The finer movements of the left hand are impaired. The movements of the spinal column are natural. The left finger joints are stiff, owing to the tense condition of the flexor muscles. There is also stiffness of the joints in the left leg, dependent on a like cause. The left trapezius is more tense than its fellow. The muscles around the left shoulder joint are smaller than those on the right, but this difference is not too marked, to be accounted for by a disuse atrophy. The circumference of the middle of the left arm is less than that of the right by an inch and a half. Between the left and right thighs the difference is an inch. These differences in size agree almost exactly with those of several cerebral hemiplegias of about ten years' duration which I have recently examined. The chest expansion is two inches and the diaphragm acts normally. As regards motion in the right hand, the patient says there is no actual loss of power, but it is not so strong as it was before the injury. The dynamometer shows a difference of nearly a half on the two sides—right, 65; left, 35. In walking, the patient makes a mowing movement with his left leg in characteristic hemiplegic style. There are slight fibrillary twitches of the muscles of both shoulders, running down into the arms. These also are more marked on the left. All muscles respond readily to mild faradic currents. The right knee jerk is active and the left considerably exaggerated, and a clonus may be easily elicited on the left side. While the superficial reflexes on the right side are preserved, on the left the cremasteric reflex is diminished and the abdominal could not be obtained. The left wrist and elbow jerks are active and are obtainable on the right. The right pupil dilates slightly on irritation in the suprascapular fossa; on the left not at all. There are no sensory changes whatever on the left. The muscular sense, as determined by distinguishing similar objects of different weights by assuming certain muscular positions at command and by telling in what position the muscles are, is everywhere intact. The following description, amplified by the charts, applies only to the right side, including right side of genital organs. The sense of touch and pressure is impaired below a line drawn horizontally from the lower border of the thyroide cartilage in front to the fifth cervical spine behind. The impairment of tactile sensibility is so slightly marked that it gives but few subjective symptoms, and in fact the patient's first knowledge of sensory involvement was his inability to distinguish between hot and cold water. The localization of touch is everywhere good. The loss of temperature sense extends below a curved line drawn from the third rib up over the shoulder, which descends again on the back to the third dorsal spine. This loss is more marked, and has become but little less since the injury. Analgesia, which is fairly complete, has still another distribution. It is present below a line which, beginning at the inner border of the clavicle, runs parallel with this bone for a third of its length, and then dips down for one or two inches and then ascends again over the shoulder and continues to the sixth cervical spine. The change in these anesthetic areas, although present at the limits given, becomes most marked about an inch and a half below the superior boundary. There is not now, nor has there ever been, any hyperesthesia. The absence of all atrophy, other than a disuse atrophy, indicates that the anterior horn is but little, if at all, involved. The absence of inco-ordination and presence of muscular sense would seem to indicate that the posterior median columns were intact. The motor change—viz., hemiplegia with contractures, increase of deep reflexes, and diminution of superficial reflexes—points clearly to a descending degeneration in the pyramidal tract. In fact, the motor symptoms are identical with those that might be furnished by a cerebral hemiplegia, even to the extent that the leg recovered more completely than the arm.

This case makes an interesting contribution to the localization of sensation of the cervical segments. Injury of the entire cord above the fifth cervical segment is immediately fatal. Gowers's case (with autopsy), in which a pistol bullet lodged between the atlas and axis and contused the right anterior half of the third cervical segment, is the highest lesion of the spinal cord reported in which examination of the various resulting symptoms had been made ante mortem. But in his case, while there followed a right spinal hemiplegia, the resulting left-sided sensory symptoms were incomplete. In the absence of recognizable injury to the anterior horn in my case there is some difficulty in determining the exact segment implicated. The knife blade entered, however, pretty surely in the immediate region of the atlas and axis; these vertebrae surround the second, third, and fourth cervical segments. From the fact that in lesions of the fifth cervical segment, hyperesthesia extends over the top of the shoulder and in the region of the suprascapular nerves,
Starr infers that this area represents the sensory distribution of the fourth cervical segment. The anaesthesia of this case corresponds very closely to these limits, and so furnishes additional evidence for the correctness of Starr's inference. Certain peculiar symptoms in Gower's case led him to think that the sensory fibers have a different arrangement in the cervical cord than in segments lower down. In his case there were nowhere observed any diminution of tactile sensibility or any impairment of muscular sense. The sense of pain was diminished, but only below the left nipple. From this Gowers concludes: "It is to be assumed, therefore, that the sensory path from middle and upper cervical nerves only crosses at the highest point of cord, above level of (present) injury." Turner, from his experiments on monkeys, was led to believe that the course of tactile sensation for the arms passed up both sides of the cord, while the fibers for pain and temperature sense decussated entirely on entrance. In support of this view he adduces some of Brown-Séquard's cases of injury to the cervical cord, where there was a bilateral anaesthesia, and one of Hoffman's cases, where there was loss of tactile sensation on the paralyzed side as well as on the side with the analgesia and thermo-anaesthesia. Now the different experiments on the sensory tract of animals are contradictory, and Brown-Séquard's cases appear to me hardly conclusive, while Hoffman's case was evidently (and so explained by himself) one where the posterior columns of both sides were involved. In the case which I have just described, where the lesion is certainly as high as the fourth cervical segment, the resulting hemianaesthesia has the characteristics of a clinical hemisection of the cord at lower levels—viz., intact sensation of the paralyzed side, diminution of tactile sensibility, with loss of pain and temperature sense on the opposite side. So the evidence that the fibers for tactile sensibility for the arms and clavicular regions have a different arrangement than those for lower areas appears insufficient.

Case II. Right Side.—Diminution of tactile sensibility; analgesia; thermo-anaesthesia; deep reflexes present; superficial reflexes active; no loss of muscular sense.

Left Side.—Stab wound of the neck; myosis; loss of cilio-spinal reflex; paralysis, with contractures of arm and leg; loss of superficial reflexes; exaggeration of deep reflexes; no loss of muscular sense.

The second case, a patient of Dr. Morrell, of Yonkers, whom he has very kindly allowed me to examine, is very similar to the one just described. This man was stabbed in August, 1892, in the left side of the neck, well up. He recovered quickly from the traumatism, and shortly afterward commenced to regain power in the left side, which had been paralyzed. The leg recovered more than the arm. He now presents a left spinal spastic hemiplegia, with loss of superficial reflexes on paralyzed side, but with activity of these reflexes on the other side. There is left myosis and loss of left cilio-spinal reflex. There is no loss of muscular sense on either side, and no sensory symptoms have ever been observed on the left side. On the right side there is diminution of sense of pain and temperature. This analgesia and thermo-anaesthesia is marked in the leg and abdomen—much less so on the arm and trunk. There is also some diminution of tactile sensibility. Owing to the slight impairment on the upper extremity of these three forms of sensibility, it is impossible to define exactly the superior limit of involvement. However, the impairment for all three begins at about a line drawn from a point in the middle of the sternum, two inches above the nipple, which ascends over the shoulder and then descending slightly continues to the vertebra. This area of sensory loss corresponds to the distribution of the fifth cervical segment.

Case III. Right Side.—Paresis, with slight contractures of leg; no loss of muscular sense; cremasteric reflex present; abdominal reflex absent; knee jerk exaggerated; clonus.

Left Side.—No loss of touch; analgesia; thermo-anaesthesia; no loss of muscular sense; cremasteric reflex present; abdominal reflex present; knee jerk absent.

This case is that of a man whom I saw about a year ago in Professor Starr's department at the Vanderbilt Clinic. He presents the symptoms of a right-sided lesion in the lower dorsal and upper lumbar cord. His own history or that of his antecedents throws no light on the etiology. He is thirty-seven years of age, a machinist, married, and a resident of Newark. He is a man of temperate habits and more than ordinary intelligence. He denies syphilis, and no evidences of it are to be found. The disease commenced about a year and nine months ago and has been slowly progressive. He is a man of robust frame, well nourished, and symptoms of disease of his vegetative organs are not obtainable. He is more irritable than formerly. The only evidences of nervous disease are found in the lower part of the abdomen, and in the legs. The motor disturbances consist in weakness with some stiffness of the right leg. His gait, as observed in the right leg, is paretic rather than spastic. There are no hypertrophy or atrophy, no fibrillary twitches, no inco-ordination, no pains or hyperesthesia. On the left side, below a line drawn almost horizontally from the mamillicus to the vertebral spine behind, exists a well-marked analgesia.

* Starr. Brain, 1894.
† Gowers. Diseases of the Nervous System, 1892.
‡ Turner. Brain, 1891.
and below a line about an inch inferior to this one there is well-marked thermo-anesthesia. On neither side is there any impairment of sensation for contact or localization of touch, and muscular sense is everywhere normal. (Muscular sense was tested by simply having the patient determine with closed eyes the position of the limb.) The cremasteric reflexes are present on both sides, and while the left abdominal reflex is present the right is gone. The left knee jerk is gone while the right is active, and there is a slight clonus on the right side. There is some loss of bladder control and some lessening of sexual power. The bowels are somewhat constipated. The case appears to me as one of right unilateral gliosis of the lower dorsal and upper lumbar region.

These three cases of unilateral lesion of the spinal cord agree in most respects with the cases, about seventy-five in number, which have been reported since Brown-Séquard’s first description. The motor disturbance has generally been one indicative of degeneration in the pyramidal tract—viz., paralysis, with spastic rigidity, but no marked atrophy. In some cases the anterior horn escapes injury; but from the now established fact that most muscles have a cellular representation in more than one segment, and as only a small portion of any one segment would be injured by a knife blade, it is fair to suppose, at least in cases resulting from stab wounds, that even if the anterior horn is involved, the functions of the destroyed cells are assumed by the uninjured cells of the affected segment, together with the cells of the other segments which are together devoted to any one muscle or muscle group, and so prevent recognizable symptoms of cell death in the anterior horn. There is on the side of the lesion an increased excitability of the deep reflexes while the superficial reflexes are diminished or lost.

In both of my cervical cases, in common with most reported cervical cases, there is myosis on the injured side, and in neither is a ciliospinal reflex obtainable on the affected side. Hyperesthesia and pain on the paralyzed side, a common and puzzling symptom, was present in but one of these three. The fact that fibers for touch, pain, and temperature decussate at slightly different levels is illustrated in the accompanying charts. Köhner* observed that tactile sensibility was involved higher than that for either pain or temperature. In my cases this difference is notable, the order of involvement being, from above downward, touch, pain, and temperature. In a case of spondylitis involving half of the cord, Rosenthal† found thermo-anesthesia two spaces higher than analgesia. His patient finally recovering, the restoration of sensation, in point of time, was touch, pain, and temperature.

These unilateral lesions of the spinal cord prove, with a fair degree of certainty, that the fibers for pain and temperature undergo complete decussation immediately on entering the cord, and proceed uninterruptedly upward on the opposite side. The conduction of sensation of temperature, as the early loss of this sensation in syringomyelia indicates, takes place probably in the gray matter. Painful impressions may be transmitted in this part also. Gowers‡ infers from his case that they go in the ascending lateral tract, but as in this case the gray matter, as well as the ascending lateral tract, was involved, it can not be excluded as a means of conduction of this form of sensation. The loss of muscular sense is the most uncertain of the symptoms of Brown-Séquard paralysis. It is retained in all of our cases, and in only a few of the reported cases has it been satisfactorily recorded. Its loss is generally believed to occur on the paralyzed side. Ferrier§ reports a case of syphilis in which loss of muscular sense occurred opposite the paralysed side and on the same side as complete tactile anesthesia and diminution of the sense of pain and temperature. The value of this observation appears to me to be invalidated by the fact that a temporary paresis as well had preceded the sensory loss on this side. Also the complete loss of touch is so extremely rare in unilateral lesions that it of itself would suggest a bilateral involvement.

From this case, together with the results of experiments on animals, Ferrier believes that the muscular sense fibers undergo an immediate decussation on entering the cord. The correctness of this view, in man at least, is hardly upheld by the reported cases of unilateral lesion. From the pathology of tabes we infer that the muscular sense, at least in so far as the sense of posture and co-ordination is concerned, is transmitted by the columns of Goll. This is generally believed for man, although the experiments of Ferrier and Beechterew|| seem to prove that it is not true for monkeys. These results, however, do not agree with the earlier researches of Schiff, nor entirely with those of

‡ Loc. cit.
§ Ferrier. *Crawfurd Lecture*, 1890.
|| Beechterew. Quoted by Ferrier, loc. cit.
Gotch and Horsley. Between the fibers for muscular sense and those for tactile sensibility there seems also to be a very close relation. While in unilateral lesions of the cord both of these sensory functions are often unimpaired when the muscular sense remains intact, I find but one case in which the muscular sense was interfered with without disturbance of tactile sensibility. This also was a case of sclerosis, a form of growth in which the fibers of ordinary sensation are often left unimpaired. Also the fact that in uncomplicated cases there is so frequently a loss of ordinary sensation in the legs lends force to the theory that the columns of Goll transmit some sensory impressions. This view is strengthened by the two following cases.

Hoffman‡ reports a case in which he inferred from the direction of the wound that the posterior columns of both sides and the white matter of the left side of the cord were involved. The sensibility to touch was diminished in the left leg and there was a right-sided impairment of this sense. Müller* also reports a case quoted in Körner's article, in which a complete hemisection of the cord, together with division of the posterior columns of the other side, resulted in complete loss of touch. Edinger believes that the sensations transmitted by the columns of Goll undergo decussation in the medulla. That all the fibers for tactile sensa-
tion do not cross in the cord, at least at levels of recorded injuries, the cases of Brown-Séquard paralysis would seem to prove; for when, in lesions of the cord, this function is entirely lost, there has been a bilateral involvement.

I can find no cases in which this sense was more than impaired, where the injury was certainly limited to one side; and, in fact, from the want of cases of complete cerebrospinal hemianesthesia there is no proof that a complete decussation of them occurs anywhere. The fibers which cross immediately on entrance are probably somewhere in the white matter of the lateral columns outside of the pyramidal tracts.

60 West Fiftieth Street.

HYPNOTISM AND CRIME.
A REPLY TO MR. THOMSON JAY HUDSON.
BY WILLIAM LEE HOWARD, M.D.,
BALTIMORE.

For people altogether ignorant of the practical realities of hypnotism, Mr. Hudson's paper in your issue of January 26th may be conclusive; but there are existing facts to-day that I have in my possession which have an eviden-
tial value as showing great gaps of accuracy in Mr. Hudson's positiveness. It is with no spirit of opposition or jobation that I desire to point out a few errors in Mr. Hudson's predications. Per contra, it is a pleasant duty to thank one of a brother profession for calling attention to a subject that must ultimately be brought daily before medi-
cal and forensic circles. Four times in the past year I have been consulted by the courts in criminal cases—two of murder, two of seduction—the pleas of the defense being hypnotism; in one of the latter cases the pretense was set up by two young girls of seduction under hypnotic sugges-
tion by a physician. As these cases are now on trial it does not behove me to comment upon them.

I shall not attempt to go into the subject of hypnotism any further than to point out a few errors in Mr. Hudson's statements—errors that are shown by some of my practical experiments. I fully agree with Mr. Hudson as to the inefficiency, from a medico-legal view, of the value of "laboratory experiments," so I shall not refer to them. Mr. Hudson also deserves the thanks of the profession for his criticism of the notorious French laboratory experimenter and the ludicrous English writer. Credulity is sometimes stupid; but irrational incredulity may occasionally be even more so.

Mr. Hudson says: "It is also believed that in the hypn-
otic state a person is under the absolute dominion of the will of the hypnotist, and can be compelled to perform any act however repugnant to his feeling or his conscience."

In exceptional cases this is true, as I know that some subjects are absolutely "under the dominion of the will of the hypnotist." I say in exceptional cases this is true; and the law must cover these exceptional cases, as it will be in these exceptional cases that the question of criminal acts will arise. B. B.'s was one of these exceptional cases.* After stealing Dr. Brinton's watch he was brought out of the somnambulistic state, and when the watch was found upon him the shock was so great that for several days he was in a state bordering on mania. It was with great difficulty that I could bring him back to his normal condition. To be frank, I doubt if he will ever fully recover from the shock.

"It often happens in the course of experiments [the Italics are my own] in hypnotism two contrary suggestions will be made at the same time. The immediate result is that a great distress of mind is inflicted on the subject, and it often results in bringing him out of the hypnotic state with a severe nervous shock. Where the latter result does not follow, the stronger suggestion necessarily prevails.† True; and it is just these stronger suggestions, which Mr. Hudson admits' sometimes prevail, that are liable to cause the subject to commit criminal acts if they are suggested to him by one of criminal intent. When Mr. Hudson mentions that in the course of the experiments two contrary suggestions may be made, he undoubtedly refers to "laboratory experiments." As I said at the commencement, we will leave those well-known experiments out of the question. It is undoubtedly true that in those experiments the subjects know that they are surrounded by friends and presumably honest men, and that no harm can come to them; so they carry out all the farcical suggestions.

Now, let us take those whose only contrary suggestion

* For a full report of this case see a paper read by request at the meeting of the Virginia State Medical Society, September, 1892.
† See an article in the New York Medical Journal for July 23d 1892.
is a self-suggestion, such as a determination not to be hypnotized, and those subjects total strangers to you and found unexpectedly anywhere, at their place of business or on the street.

Police officer N., of this city, was walking with me on his beat one evening when we met a fellow officer. Officer N. said to officer D.: "D., you had better look out; Dr. Howard will hypnotize you." "Oh, I know he can do it to some people," replied D., "but I'll be d----d if he can do it to me." Without giving him a moment's warning I said: "D., your eyes are shut; your eyes are tightly shut; you can't open them. You are a log of wood; you are falling down. There, you hear nothing; you feel nothing." The man was prone on his back. Officer N. had fled; it was too much for him; but he called out to me: "For God's sake, doctor, wake him up; the sergeant will be here in a moment." Upon my promise not to hypnotize him, officer N. came and strenuously and pitifully tried to arouse officer D. He might as well have tried to arouse the lamp-post. He told him that if the sergeant saw him it would be all up with him. Certainly, D. would have arisen under the circumstances had he not been completely "under the will of the hypnotizer." I brought him out of the hypnotic state just as the sergeant was coming up the street. Some weeks afterward I met D. on the street. On my going up to him he said: "Doctor, I am really afraid of you, and if you attempt to hypnotize me I will club you." He had his club in his hand. I said, "You can't move your arm." He made an effort to do so, and found that it was powerless. Then he tried to take the club in his other hand, when I suddenly clapped my hands in front of his face and told him that he could not move, I could then do as I pleased with him. The mere loss of the power of his arm was sufficient to produce complete hypnosis. This is rare, I admit, but it is to these exceptional cases that I wish to call attention to show that hypnotism has a place in medical jurisprudence. In this case, remember that the subject was an officer accustomed to obey. This accentuates Moll's statement—viz., "Persons accustomed to obedience can be hypnotized at the first attempt even against their will, and without the necessary straining of the attention." *

One evening I walked into a public place and found Dr. Burton Stevenson, of this city, and several friends. As often happens when I am around, the subject of hypnotism was brought up. With the exception of the doctor, all were strangers to me. One of the gentlemen scoffed at the subject as an actuality, and alleged that no one could hypnotize him. He had not time to repeat his words before he was completely under my control. It is not necessary to go into the details of how I completely turned the tables upon him.

I finally told him that he must go out to a certain lot, where he would fall down and neither hear nor remember anything. It was a cold, rainy night, about twelve o'clock, when we found him as I had ordered. He was dressed in evening clothes. With the exception of Dr. Stevenson, all the party were badly frightened. I brought him out of the hypnotic state, and have seen neither him nor the other gentlemen since. He still adheres to the statement that his friends are lying to him when they tell him that he was hypnotized and asleep in the lot. However, he has questioned Dr. Stevenson, and can not account for the ruin of his clothes.

A similar case happened in the caf' at the Equitable Building here. In the presence of a large number of gentlemen I walked up to a stranger to all and told him that he could not move his arm; that it was paralyzed; that he could not lift it. Finding that he had, in fact, lost the power of the arm, his facial expression told me that I had got complete control of him. After convincing the few

* See the paper read before the Virginia State Medical Society.
gentlemen that were now left—for it is an amusing sight to
see people slyly get away from my presence—I told the man
that he must pay me the money he owed me. He gave me
readily a large roll of bills, and, at my suggestion, told
those present that he owed it to me. I told him, after an
interval during which he was becoming suggestively drunk
on water, that I owed him money, and that he must give
me a receipt for it. The name signed to the receipt aston-
ished me, as it was the first intimation I had had of who
the man was. I then told him that he was drunk and must
go home and sleep, and would not awake until six o'clock
that evening. He had had nothing but water to drink, and
I have proof that he greatly shocked his family and friends
by his conduct, as he had up to that time stood above re-
proof among his large number of acquaintances. The sug-
gestion to sleep was carried out to the hour. Often have I
taken subjects like this at random. I might continue, but
these are sufficient for my case. That these are exceptional
cases I admit, but they nevertheless prove what I now
maintain, that subjects can be hypnotized against their will.
If this last person had been forewarned, it is very possible
that I could not have done anything with him, and he
would have been able to have one of those contrary sug-
gestions Mr. Hudson so emphatically impresses upon the
minds of his readers. But the expert hypnotist will not
give the subject a chance to call forth "the instinct of self-
preservation" if he contemplates using the subject as an
automaton to carry out his ultimate object.

It will undoubtedly seem very strange to some persons
how I can be so successful in getting such complete sub-
jects. If I am in company with several people I can in-
stinctively pick out my subject. This faculty may be due
to practice and experience, or perhaps to some indefinable
intuition. I do not know. Remember, also, that I am not
mentioning my numerous failures.

Mr. Hudson further says: "It has often been said that
a criminal hypnotist would have the power to induce the
subject to produce abortion or commit suicide by means
of suggestion. The instinct of self-preservation would
constitute a potent factor in case of an attempt to instigate
the commission of a murder. The subject would instinct-
ively reason up to the consequences to himself in case of
detection."

I think I have shown why this statement should be modi-
fied. The idea that only those known to have evil and crimi-
nal instincts can be made to commit crimes under hypnotic
suggestion is probably true in a general sense. However,
we must not forget that most of us have some latent or
undeveloped animal or immoral germ hidden and inactive
in our psychical organization. Sometimes the proliferation
and recrudescence of this germ is seen in our progeny, or
else, as far as we know, kept quiescent by environment, edu-
cation, and the fear of the ultimate consequences should we
transgress the laws laid down by our fellow-men. Now, if
the subject is one of these exceptional cases that I have
given, we can, by inhibiting this "instinct of self-preserva-
tion," and his tendency to "instinctively reason up to the
consequences to himself," work upon what is practically
virgin soil, with the exception of the latent germ men-
tioned. By repeated hypnotic and post-hypnotic sugges-
tion I believe these persons can be made to commit any
crime. If this is true, then, reversing the order of proce-
dure, we have a basis for an intellectual and moral ortho-
pedia.

While there is some difference of opinion regarding this
commission of crime under hypnotic control, I am in accord
with the following authorities: Motet, Ladame, Dumont-
pellier, Guermonprez, De Grasset, Forel, Liégeois, Semal,
of Belgium, Tuckey, Moll, Gowers, Bourru, Binet, Kraft-
Ebing, Dessoir, Bjornstrom, and numerous others.

An eminent member of Mr. Hudson's profession, Judge
Abram H. Dailey, says:* "A person who is thoroughly
hypnotized is under the absolute control of the hypnotizer;
the subject, for the time being at least, can be made to do
almost anything within the power of the man at the com-
mand of the hypnotizer."

It is not necessary to more than state the well-known
fact that, once you have hypnotized the subject, subsequent
work offers few if any difficulties. But the conesthesion,
on which depends the ego or personality, is the last part of
the organization to be affected.

As I shall in a short time give to the profession the re-

tult of my investigations regarding the legal status of hyp-
notism, I will not here trespass on the domains of Mr. Hud-
son. I wish to say, however, that the sooner the two pro-

cessions come to some understanding in the matter, the
sooner can we stop all this ridiculous and sensational stuff
that is daily exploited in the press. We can also put a
stop to the silly pleas of hypnotism as a defense, which
bid fair to deluge our courts to such an extent as will ulti-
mately mix them up in a bewildering maze of incongruities.
We can soon stop all this, for, as Kraft-Ebing says, hyp-
notism, as a biological phenomenon of Nature, offers symp-
toms empirically true, clear, and objective, the proof of
which is decisive.

CANCER OF THE STOMACH:
ITS PHYSIOLOGICAL TREATMENT.†

By DANIEL E. KEEFE, M.D.,
SPRINGFIELD, MASS.

In looking through the leading text-books on the prac-
tice of medicine one is surprised at the panegyric matter
on the treatment of cancer of the stomach. It is usually
dismissed with a few sentences. I quote from two of the
most recent and leading ones as samples: "Treatment
altogether palliative. The indications are to make the pa-
tient comfortable by relieving pain and vomiting. The
diet may be determined by the experience of each patient.
In the majority of cases alcoholic stimulants in moderation
are beneficial. When the pain becomes severe morphine
may be administered hypodermically. If at any time the

* Hypnotism in Medico-legal Jurisprudence. By Judge Abram
Dailey, President of the Medico-legal Society. Medico-legal Jour., De-
cember, 1893.
† Remarks made before the Hampden District Medical Society, dis-
cussing cancer of the stomach.
stomach becomes overloaded, its contents may be carefully removed by the stomach pump. Aloe for the constipation, sulphite of sodium and oil of cajuput for the flatulence. Bismuth subnitrate during the whole course of the disease, combined with soda, conium, and stramonium, are recommended. If the stomach entirely rejects food, rectal alimentation may be resorted to." (Loomis, Practical Medicine, p. 246.)

"Palliative measures are alone indicated. Diet of readily digested substances of all sorts. Many do best on milk alone. Washing out the stomach when there is obstruction at the pylorus is particularly advantageous, and is by far the most satisfactory means of combating the vomiting. The excessive fermentation is also best treated by lavage. When the pain becomes severe, particularly if it disturbs the rest at night, morphia must be given. One eighth of a grain combined with carbonate of sodium (five grains), bismuth (five to ten grains), usually gives prompt relief, and the dose does not always require to be increased. Creosote (one to two minim) and carbolic acid are very useful." (Osler, Practice of Medicine, p. 384.) And we find no more thorough discussion of the subject or more minute directions in the larger works, such as Pepper's System or Reynolds's System.

It may be asked, Are not those given, if carried out intelligently, complete and far-reaching enough? Do they not embrace all that is essential, and what more can be said? Is not the disease necessarily and rapidly fatal? All this may be true so far as the great essentials of medication are concerned, but it is by attention to details, particularly those applying to alimentation, and the thorough understanding of the great principles underlying them, that we are often enabled to achieve success when otherwise our efforts must result in failure.

We have no medicine that will cure or even retard to any extent the progress of the disease; still, there are those who think that cundurango and arsenic do exert such influence. Clinical observations, however, do not support such beliefs. Why medicate at all then? Because by so doing we make our patient more comfortable. For this reason it is well to remember that in medicine we have an important auxiliary. Thus cundurango, morphine, conium, and belladonna control the pain. Bismuth subnitrate, dilute hydrocyanic acid, ice, cocaine, limewater, and alkalis alleviate the vomiting. Antiseptics, such as boric, carbolic, salicylic acids, cresote, and oil of cajuput lessen the eruption of gas and control the fermentation and fever, while all these medicines are assisted in their action by washing out the stomach through a soft rubber tube. We must remember the limitations of this medication, however. When we appreciate these facts, and remember that the duration of the disease is from three months to a half to three years and a half, it must be apparent that our only hope is in physiological alimentation. We may hope by this means to compel the minimum more nearly to approximate to the maximum, and perhaps extend the maximum duration to a certain degree. We can, I feel sure, at least make the short time that remains to the poor sufferer more tolerable.

Before entering into a description of our conception of the principles involved in the treatment of cancer of the stomach and its proper alimentation, it seems proper to review briefly the functions of the stomach and bowels, in so far as they relate to digestion. We shall thus be enabled to more intelligently judge of the correctness of the principle to be formulated and to select a dietary most suitable to the demands of the system under its altered and abnormal conditions. It will be remembered that experiments and observations on Alexis St. Martin and others demonstrated that when food entered the stomach it was carried from right to left to the cardiac end, thence along the greater curvature to the pyloric end, thence along the lesser curvature back to the starting point. This peristaltic circulation or churning was continued until all the alimentary matters were reduced to a diffusent condition, the liquid portion passing through the pyloric opening into the duodenum, not all at once, but a little on each circuit, until all had passed through. The stomach concerns itself principally with the digestion of the albuminoids, converting them into peptones. With the aid of the ptyalin of the saliva it hydrates the starch of the carbohydrates, especially of bread, dissolving out the gluten or albuminous part and precipitating all the starch not changed by the ptyalin. It also digests the casein or albuminous part of milk. In the intestine the four pancreatic fermentations, aided perhaps to a certain extent by the bile and intestinal juices, digest principally the carbohydrates, such as starches, sugars, and fats, but also albuminoids. Thus we observe that all sorts of nutritive materials are digested in the bowels, though it may be questioned whether the albuminoids are as rapidly, efficiently, and economically digested as in the stomach. In view of these facts we are, I think, justified in concluding that, were it possible for us to introduce liquid foods directly into the duodenum, we could get along without the stomach for a considerable time and with tolerable comfort. It follows from these premises as a logical conclusion that stomachal digestion of pristine power and completeness is not absolutely necessary, provided the foods be in a liquid or semiliquid form. We are now prepared for the statement of the physiological law and its application. It may be stated in these terms: The activity of the circulation in any organ, viscus, or member of the body bears a direct ratio to the functional activity of the said organ, viscus, or member. That the greater the circulation, the greater the metabolism and the greater the nutritive supply. It follows as a natural corollary to this, and it is a fact proved by clinical observation, that the growth of cancer, indeed I may say of all tumors, is rapid in proportion to the strength and rapidity of the circulation and nutrition. This is illustrated by the slowness of such growths in the aged and feeble, whose circulation is weak, whose nutritive powers are almost nil. Inactivity means little metabolism, little nutrition, and small circulation; while great activity is synonymous with large blood supply, great metabolism, large supply of nutrition, and rapid growth. The practical deductions to be drawn from these facts in the treatment of cancer are, it seems to me—(a) Give the stomach a maximum of rest and a minimum of activity so as to
keep its blood supply as small as possible. (b) Treat it as nearly as possible as though Nature intended it, like the esophagus, merely as a conduit for the alimentary matters to the duodenum. To this end let all our foods approximate as nearly as possible the fluid state, so as to permit of their easy and speedy passage through the stomach and so avoid irritating it or setting up and prolonging its persisting action. (c) They should consist as largely as possible of carbohydrates, materials that the stomach takes little or no part in digesting. (d) These rules should be put in practice as soon as the disease is diagnosed and not wait until the end is near at hand. (e) In carrying out these rules alcoholic stimulants are to be avoided until the time arrives when little or no food can be taken, when the end is a question of a few days or weeks. Then all rules may be suspended and taste and comfort only considered. For, notwithstanding that stimulants are recommended by some of the best men in the profession, they cause hyperemia of the stomach, and hence are unphysiological in this disease.

I may now indicate some of the articles that seem to me most suitable for our dietary, many representing a whole class or family, for it is simply impossible to mention all in a field almost limitless. I only regret that I am compelled to mention so many pharmaceutical preparations, but "the truth must be spoken though the heavens fall." I mention as first in importance malt extracts, such as maltine and Trometer's extract, for the reason that they contain a large amount of carbohydrates and an albuminoid in an easily assimilable form, and also promote the digestion of other carbohydrates; oyster, clam, and chicken broth; beef and mutton soup; fresh boiled fish sparingly, such as oysters, trout, cod, and haddock; fresh meat in limited quantity, such as pulp and scraped beef and mutton, powdered and liquid beef peptonoids, and, when there is much eructation of gas, liquid beef peptonoids with creosote is a most suitable preparation; bovine and beef tea, either made from the extract or from the beef direct; fats—such as butter, cream, olive (salad) and cod-liver oils; ice cream, soft-boiled eggs or raw eggs whipped with sugar and water, milk and kumyss; steamed custard, stale bread, bread and milk, bread and butter, boiled oatmeal, rice, corn starch, sage, tapioca, and macaroni. This enumeration would be sadly incomplete if I did not mention a class that I consider more important than any yet mentioned—namely, the predigested infant and invalid foods. I may mention as a representative of this class Carnrick's soluble food, containing in addition to the salts, digested and soluble wheat starch and maltose or starch sugar, sugar of milk, and evaporated milk. This class should form an important element, if not the largest one, in our dietary for this class, since they are not only very grateful but also very nutritious. Indeed, they seem more nearly than any other class to be the food exactly suited to this disease. For drinks, tea, chocolate, cocoa, lime juice, Seltzer, milk, and kumyss, and, bearing in mind what I have before said as to stimulants, a little wine may be admissible at dinner or for the promotion of sleep—any dry wine, such as hock, claret, catawba, Rhine, Hungarian, or even sherry.

In conclusion, I am very strong in the belief that the physician who will at an early period in the disease carefully formulate a dietary for his patients on the physiological principles just described will experience greater satisfaction and contribute more to the comfort and the prolongation of the lives of those having gastric cancer than by a like attention to any system of medication only.

ATAXIA

AS A SYMPTOM OF DISEASE IN THE CEREBRO-SPINAL SYSTEM.

By D. B. MCCARTIE, M. D.,
NEWARK, N. J.

Ataxia is a symptom of disease or derangement of the nervous system almost as prominent as abolition of function or paralysis. It is a notable feature in many diseases. It should not be always associated with ataxia occurring in the lower extremities and known as "locomotor ataxia," since the rare and hereditary form of ataxia shows that it has much wider applications and must invade a much greater surface of diseased area than is usually ascribed to it when associated with the disease "tabes dorsalis," for besides the inco-ordination of movement of the lower extremities there is present inco-ordination of the eye muscles, or nystagmus, and inco-ordination of the tongue and laryngeal muscles, which causes impairment of speech. We find ataxia also combined with paralysis in an almost distinct class of cases, the difference being that the paralysis and ataxia occur pari passu and are known as "ataxic paraplegia."

Ataxia is found most commonly in the disease called locomotor ataxia, but it is a well-marked feature also in ataxic paraplegia and in Friedrich's disease, or the hereditary form. Again, we find it well marked in disseminated sclerosis, where the ataxia occurs on voluntary movements of the muscles of the extremities and the muscles of the eyes, larynx, and tongue. It occurs in general paralysis of the insane, interfering with the gait and proper action of the tongue. It occurs occasionally in neuritis, and has followed injuries to the cord and brain. It is especially prominent in disease of the cerebellum, and occasionally in tumors situated in the cerebro-spinal system. It has been seen as a sequel to diphtheria and alcoholism, also arsenical poisoning. It sometimes occurs in hysterical patients, and lastly is found as a functional derangement of the nervous system (vide case at end of article).

Many theories were brought forward to explain the curious muscular irregularity called ataxia; some deal with the physiology of the cord and explain the inco-ordination occurring because of disease in the posterior columns of the cord, whereby the sensory impressions from the muscles to the brain are cut off. This presupposes a co-ordinating center set aside in the cerebellum and acting on the motor impulses by a co-ordinating action. Many other theories exist which throw little light on the subject, and it is therefore unnecessary to repeat them here. But, no matter how it occurs, it is evident that inco-ordination means lack of force and not perversion of normal force.
theory can throw light on a force supposed to exist in the cerebellum which regulates impulses coming from the brain. It looks more feasible to consider that the impulses are misspent or perverted, and that the muscles act irregularly in response to irregular nerve currents, since their paths of conduction are interfered with.

The co-ordinating action of movement is a far more intellectual act than the volitional impulse itself; therefore it would be contrary to all our knowledge of the brain as a higher center to place the intricate and highly intellectual act of co-ordinating movement in a lower center, as the cerebellum.

Such an intellectual act as violin-playing would not be very high in the scale of intelligence if it depended on the correcting action of the cerebellum—that is, according to our knowledge of the seat of intellect in the brain. Our acts are highly intelligent, since they portray the thought which arises in the brain, and consequently are co-ordinated from the first and require no additional feature save proper conduction.

When anesthesia of the lower limbs is present there is an inability to stand steadily, especially if the eyes are shut. This has been thought to be the cause of inco-ordination, but anesthesia occurs independently without causing ataxia. Leyden maintains that since guiding sensations contribute to due execution of movement, the ataxia is merely a consequence of interruption in transmission of such sensations along the cord; but Pagge quotes a case in which there was perfect anesthesia and even loss of "muscular sense," but no inco-ordination. Another case is instance of multiple tumors on the posterior nerve roots in which ataxia existed, as proving that interruption of the sensory nerve currents from the muscles going to the cerebellum is the cause of ataxia; but in this case it would be very improbable that all sensory currents were cut off. It also happens that ataxia does not generally take place in partial peripheral nerve paralyses nor usually in neuritis. None the less the most maintained theory seems to be the lack of conveyance to the cerebellum or brain of the so-called "muscular sense," whatever that may be, through disease of the sensory tract in the posterior columns of the cord, or disease in the sensory nerves themselves which, through the posterior columns of the cord, are supposed to bear impressions upward to a co-ordinating center in the cerebellum.

Volitional motor impulses pass down through the motor tracts, and, being the primary elements in muscular action, do not seem to necessitate sensory phenomena from the muscle to indicate their action, so that if any irregular action takes place it may be due to the obstruction of these volitional impulses in the diseased tracts of the cord or in peripheral nerves themselves, or possibly in other parts of the nervous system. It is far more probable, therefore, that the obstruction in the cord or nerves interferes with the primary volitional brain impulse coming downward and not the loss of sensory currents from below, which require the complicated mechanism of transmission up to the brain and down again, for how these impressions come down is again a problem, since they do not arrive at the muscle

through the motor tracts, for disease of these tracts does not necessarily imply inco-ordination.

The sensory theory implies that all our actions are automatic and consequently involuntary, since they depend on the sensations in the muscular tissues. But if the volitional impulse comes primarily from the brain it would upset the idea of its depending and acting on the muscular sense. The muscle sense calls for certain action, and without it the motor impulses are inco-ordinated; in this case the same argument applies to the muscles of the eye, the tongue, and the larynx, where the connection of the posterior columns of the cord and the cerebellum are not evident. Thus, in insular sclerosis and general paralysis of the insane the ataxia is quite marked, without disease of the posterior columns of the cord, the sensory nerves of the muscular tissue, or the cerebellum.

The order of lesion appears to be:
1. Paralysis, due to complete destruction or obstruction of nerve fibers or centers.
2. Spasm, due to partial scleroses (spastic paraplegia).
3. Ataxia, due to obstruction in some nerve bundles and consequent perversion of the nerve currents as regards time and place.

It is most probable that a muscular action co-ordinates itself primarily from its first origin in the brain or cord, and requires no muscular sense to direct its action except the perfect transmission of its force, irregular transmission giving irregular results; tremor being a fine form of obstruction to transmission, ataxia a rougher form, while spasm may be complete loss of the nerve current to the flexor or extensor sets of muscles.

From these views it may be concluded that the disease called locomotor ataxia has a wider field of lesion than the posterior columns of the cord or the sensory nerves in connection with the muscles, and that we must look higher up in the brain for the cause of the inco-ordination, since it occurs in several diseases where the cord and the nerves are intact. Again, the change often affects the eye muscles and those of the larynx and tongue, which cannot be explained on the analogy of these parts to the sensory nerves of the cord.

The etiology of the disease is plain, syphilis being the cause in eighty per cent. of the cases, though its special tendency to cause a localized degeneration of certain nerve tracts is most illogical and unsatisfactory.

There is no connection between the loss of sensation in the skin and ataxia except that anesthesia increases existing inco-ordination, nor is it evident that ataxia depends on loss of "muscular sense," since in the case reported by Pagge loss of "muscular sense" occurred, but no ataxia. It is an ingenious method of explaining a difficulty, for physiology points out that the posterior columns of the cord are ascending columns, and consequently transmit impulses upward, and they are found generally diseased in connection with ataxia. It is necessary, then, to form a theory to conform with their functions; hence it is assumed that muscular sensations pass up through the posterior columns and help to co-ordinate in the cerebellum the motor impulses which come down from the brain. This would
limit all our actions; every act would then be reflex or automatic and would depend on the "muscular sense."

The same applies to the utterance of thought in speech; the expression of thought would depend on the muscular sense or automatic action of the laryngeal muscles, the eyes would follow a similar action, and, indeed, the entire muscular system. Voluntary action were impossible, for the co-ordinating act is the most intellectual feature of any act, but if it depended on the "muscular sense" it would be merely a reflex condition.

The physiology of the cord is not so well understood as to suppose that all impulses are conveyed up the posterior columns. It is a contradiction to say that the cerebellum presides over co-ordination when the conduction of these posterior fibers is upward. There may be downward fibers as well which deal with the proper equalization of nerve force, though our conception of such a co-ordinating force is vague, and, indeed, it is extremely improbable that such a registering and qualifying condition exists outside ordinary muscular action.

The fact ataxia is plain; we infer a co-ordinating force. It would be more rational to consider that all movements are co-ordinated naturally, except those obstructed in transit. This condition is rather evident in disseminated sclerosis, where the posterior columns and sensory nerves are intact, but where much inco-ordinated action occurs and where evident patches of obstruction exist. It is also manifest where tumors grow in special nerve tracts, in general paralysis of the insane, and spastic paraplegia.

The loss of the knee jerk is brought forward to explain the early interference which disease in the sensory nerves exhibits, but in the case cited in the end of this article the reflexes were much increased, though ataxia was a prominent symptom. The loss of reflex at the knee may be explained as due to loss of a downward motor current, since it often occurs when sensation is perfect.

In cases of locomotor ataxia the muscular tissue does not show loss of sensibility. If ataxia were due to the loss of this "muscular sense" most sufferers would lose the sense of muscular position; but this rarely happens. And again, where the muscular sense is lost co-ordination is preserved, as in the case cited above. The few rare cases in which paralysis of motion occurred on one side and sensory paralysis on the other side, with the extraordinary fact that loss of sense of position occurred in the leg in which sensibility was retained and was preserved in the other leg where all ordinary sensation was abolished, scarcely proves the distinct existence of a "muscular sense," for if the tactile sense was lost sense of position would also be lost. What the sense of position can mean, save contact with an external body, it is difficult to understand. But even if there was a distinct muscular sense which directs co-ordination, ataxia would commence at once if it were lost; but in the above case where crossed paralysis occurred, the ataxia only supervened ultimately (vide Gowers, footnote), and in Fagge's case it never existed at all, even though the muscular and cutaneous senses were abolished. It would be incredible to think that if cutaneous sensibility were normal the sense of position could be lost, and if ataxia depended on this loss every case of locomotor ataxia would present some loss of the sense of position. In cerebellar disease there is no loss of the sense of position, yet the patient can not co-ordinate. It is not plain, therefore, what the sense of position has to do with ataxic movements. The eye ought to be a good example of how the sense of position affects co-ordination, but in nystagmus the sight is perfect.

All voluntary movements are primary acts, but if they depended on a sensory impression they would necessarily become secondary, which would mean abolition of the will power. The finest co-ordinated movements show a cerebral influence, such as violin-playing; they are acquired with difficulty, and other mental qualities, as memory, taste, audition, and sight, are brought to bear upon the action, showing that it is a primary mental influence which co-ordinates the action and not an automatic mechanism.

Inco-ordination is possible where the posterior columns of the cord are intact, the peripheral nerves are free from disease, and the cerebellum healthy; this occurs in disseminated sclerosis, hysteria, and functional ataxia. Then we must look for the lesion higher up in the motor tracts, where obstructive lesions of this kind are found in general paralysis of the insane and in disseminated sclerosis.

The following case illustrates a functional form of ataxia. A few cases of a like nature are mentioned in Wilk's treatise on diseases of the nervous system, otherwise I can find no reference to this form of ataxia.

John J., aged forty years, laborer, married, two children, healthy. No family history of nerotic disease, none especially relating to Friedrich's disease. No history of syphilis or evidence thereof. The chief clinical history related to sexual excess. The man simply called for treatment in view of weakened sexual power. He stated that he thought an overindulgence in this respect was the cause of his present impotent condition.

Personal History.—He was always strong up to the present time. Had an attack of gonorrhea several years before. He said he thought his testicles were much smaller of late, especially the left one. On examination both testicles were very small and soft to the touch, but not painful. An ordinary varicosity was situated on the left side and was a thing of years. The present trouble had existed only about a month. It had begun by a loss of the sexual power and ended in failure in this respect. He had no other symptom. On more careful inquiry he said he felt his feet giving way on walking and his gait became uncertain. The man is of medium height, with muscles strongly developed. The grasp of both hands is powerful. There is no tremor, but inco-ordination is well marked when the patient begins to walk. He walks also very much on his heels, but has very little difficulty in turning. With the eyes closed and the feet together he sways very much. There is no loss of sensation. He has no history of pain, no stomach or bladder trouble, no headache or vomiting, no giddiness or difficulty in micturition. He is impotent. The knee jerk is much increased. The pupil acts naturally to light and distance. Speech is perfect. There is no loss of power in the muscles. After six weeks of tonic treatment and a light plaster-of-Paris jacket to support the back the patient had lost all signs of ataxia and could walk without the least difficulty. With the eyes closed he could stand steadily or, as he expressed it himself, he could walk in the dark.

The impotence remained, but all the other symptoms gradu-
BRUSH: HUNTINGTON'S CHOREA.

The careful logically. but purposeful she tended, be with hasty ing. This admission there contractions, ing. Three these from autopsy, as described by the pathologist, we a hasty autopsy, reporting as having found nothing beyond a basilar pachymeningitis. Case II.—M. B., An English widow, aged forty-six years. This patient at first denied any family history of disease, but afterward admitted that her father had had a similar condition late in life. The present trouble commenced about three years before admission with involuntary contractions of the facial muscles, and these gradually became more extensive and severe, involving in order the arms, trunk, and legs. These spasms are partially controlled by voluntary effort, and slight movements continue during sleep. The spasms are clonic in character, involve groups of physiologically associated muscles, and are most marked in the face, neck, and upper extremities, which keep her constantly grimacing and posturing. With these spasms there are also associated fibrillary contractions, partial and isolated spasms of single muscles, and there is some inco-ordination of both arms and legs. This case passed from observation unchanged at the end of three months.

The diagnosis of this condition is based upon the following points which distinguish this disease from the other forms of chorea, and most of which were well marked in these cases:

The disease is a chronic and progressive one, without tendency to improvement, but usually does not shorten life.

It is a disease of later life, usually beginning between thirty and forty.

It is more common in women than in men.

It is usually associated with mental failure or melancholia, with or without delusions.

If a generation escapes, it does not reappear in that branch of the family.

It occurs without known cause.

It begins in the face and extends downward, growing more severe.

Authorities differ as to the character of the muscular contractions; but this difference is, as we shall see, more apparent than real, as both varieties described are the result of the same lesion, the difference being due to the amount of damage done to the cortical motor cells. These movements may be clonic spasms of physiologically associated muscles, or there may be irregular clonic spasms of single muscles, or partial and fibrillar contractions may occur.

The movements are partially or completely controlled by voluntary movements and are diminished or absent during sleep. The chorea never remains localized, and there is more or less inco-ordination. The pathological findings in all the cases in which such examinations have been made point to the cerebral cortex as the seat of the lesion.

The changes found, such as an accumulation of leucocytes about the blood-vessels, degeneration of the nerve cells, increase in the neuroglia tissue, meningitis, and atheroma of the arteries, class this disease with those chronic degenerative processes of the nerve cells whose first manifestation is an abnormal activity on their part.

It is unfortunate that the chance of making a careful microscopic examination in the first case was lost; but it is not probable that even had this been done we should have learned anything more as to the pathology of this disease than we know now.

The cortical origin of the symptoms is shown by the pathological findings, by the associated mental changes, by their beginning in the muscles habitually most under the cerebral control, as the face and arms, and by their absence during sleep and arrest by voluntary movement, both of these latter being exaggerated when of spinal origin. As to the nature of the lesion, Huntington's chorea should be classed with those inherited degenerative neuromes due to some vice of nutrition which do not show themselves until the normal deterioration of the nervous system due to advanced age begins, and involving primarily the superficial layers of the cortex with consequent loss of control over the deeper layers and lower centers, and sometimes followed by secondary changes in these structures. To explain the symptoms, then, it is necessary to briefly review

* Read before the Brooklyn Society for Neurology, June 28, 1894.
a few points in the physiology and anatomical relationships of the cerebral nerve cells and the method by which muscular movements are produced in the brain.

The cells of the cerebral cortex have dependent upon their situation the power of receiving the impressions sent to them from other parts, and by the repetition of certain impressions the various nerve cells affected by it become associated into groups, as it is said, by the formation of lines of diminished resistance between them.

Such cell groups may then become further associated into larger ones, and thus habitual trains of thought and the like are formed.

After such an association has once been formed, the excitation of any part will throw the whole into activity. Impressions when once produced upon a cortical nerve cell are probably permanent, but it may be years before volition or association recall it to conscious attention.

The oftener such an association is thrown into a state of activity, the easier and more automatic does its action become.

Such cell groups may not only be thus acquired, but they may also be inherited, as shown by the mental peculiarities of certain families and by the instinctive movements in children and animals.

When such an association is so well marked that we can localize it, it constitutes a memory center.

The motor centers in both hemispheres for the simpler movements habitually act together, but those for the more highly specialized movements tend to become localized in one of the hemispheres.

Throughout the nervous system we find that certain groups of cells possess the power of controlling the actions of others, and it is to this power that we are able to stimulate or inhibit the discharges of these various centers in response to the demands of volition. Those centers which represent the highest controlling power of the nervous system are situated in the prefrontal lobes.

Everywhere throughout the cerebral cortex we find what is known as its second or sensory layer, but which is in reality its superficial nervous layer, uniformly composed of small angular cells.

It is these cells which are supposed to possess the power of inhibiting and controlling the discharges of the cells of the various centers which lie beneath them.

The sensori-motor apparatus, then, consists of the sensory layer, the cortical motor centers which lie beneath it, and the lower or spinal centers.

The motor cells of the cortical centers would discharge at regular intervals were it not for the inhibitory power of the sensory layer.

These cells in turn possess a dual power over the cells of the lower motor centers, that of stimulating them to discharge in response to volition and of, at other times, partially inhibiting the rhythmical motor discharges which these cells send out, and by which the muscular tone of the body is preserved.

Purposeful movements and not individual muscles are represented in the cortical centers, due to the inherited or acquired organization of their cells into groups, and also possibly to the anatomical arrangement by which such cortical cells control a large number of spinal ones.

The cells of the lower motor centers are, as I have said, under the control of the cortex, but peripheral impulses, if very acute, may cause so much irritation as to overcome the inhibitory influence.

In like manner muscular movements which at first required active attention may, when once originated either by volition or in response to external stimuli, from a similar organization of the cells in the lower center, be continuous without the aid of further volition. Such movements may not only be acquired but also inherited, constituting the instinctive and emotional movements.

It is evident, therefore, from these facts that any conditions such as have been found in this disease, which act principally upon the superficial layers of the cortex, according to the amount of damage done to the nerve cells, will first weaken or destroy the inhibitory powers of the sensory layer, leaving the motor cells free to discharge themselves whenever they have acquired a sufficient amount of force.

When the damage is not yet marked, a sufficient number of healthy sensory cells may remain to temporarily control these motor discharges, as when active attention is directed toward them, as in purposeful movement.

If the damage to the motor layers has not been sufficient to break up the association of cells into groups, the muscular contractions will then involve groups of associated muscles, and most markedly those most habitually under the control of the mind, as those of the face and hand.

If the degenerative changes extend to the motor cells, this associated action is by unequal damage destroyed, and we then have the irregular contractions and the fibrillary tremors from loss of control over the spinal centers, and from this latter condition also the increased reflexes and inco-ordination. The absence or diminution in the contractions during sleep is due to the abeyance of all cortical action in that condition, the movements which are found being, as I have said, of spinal origin.

The mental changes which always occur sooner or later in this disease are, of course, due to similar changes in the volitional centers and of the mechanism by which they are brought into relationship with the other centers.

339 Lafayette Avenue.

A Newly Discovered Foramen.—Dr. J. W. Hartigan, professor of human and comparative anatomy in the West Virginia University, informs us of his discovery of a foramen in the base of the transverse process of a lumbar vertebra in the human subject. This, he says, has never been noticed by any anatomist, so far as he is informed. Henle's case was one of union, by a bridge of bone, of the manillary and accessory processes, an entirely different thing.

The New York Medico-surgical Society was organized on March 4th. The officers are as follows: President, Dr. Edward J. Berningham; vice-presidents, Dr. A. H. Goelet and Dr. W. W. Van Valkah; secretary, Dr. Samuel E. Milliken; treasurer, Dr. Frederick A. Lyons.

Condy's Fluid.—A correspondent wishes to know what this is. It is said to be a two-per-cent. solution of potassium permanganate.
THE TREATMENT OF INFLUENZA.

In the Pressus medico for February 8th there is an interesting article on the clinical forms of this disease and their treatment, by Dr. A. F. Plaque. The whole article will well repay the reader's perusal, but our space will not admit of our dealing with more than the therapeutic part of it. In the common forms of the disease, without special complications, hygiene, with rest in bed, says M. Plaque, should be the foundation of all treatment. Hot drinks also may be employed. Milk is one of the best, and has the advantage of being an active diuretic. Coffee is also useful in prostration and headache. Antipyrine, in daily amounts of from thirty to sixty grains, gives good results in headache, although it sometimes increases the cough and the bronchial irritation. Tincture of aconite root, from ten to thirty drops in a day in divided doses, may be given when there are fever, general malaise, and laryngo-tracheo-bronchial catarrh, but it occasionally increases the nervous agitation. Quinine still remains, perhaps, says the author, the agent that more thoroughly reaches the disease, although it sometimes aggravates the feeling of weight in the head; this, however, is less marked with quinine hydrobromide and with the valerianate than with the sulphate. A gentle purgative is always useful during the first two or three days in cases of gastric derangement. If the thoracic symptoms are intense, manna or castor oil is preferable as a purgative.

In the common forms of the disease the most important advice to give the patient is perhaps that which deals with the antiseptic treatment of the nose, the mouth, and the pharynx. Gargling with a solution of boric acid, or with a one-per-cent. solution of chloral, intranasal applications of vaseline and boric acid, and great care in cleansing the mouth are pretty sure to prevent certain complications, such as angina, abscesses, otitis, perhaps even broncho-pneumonia, and will certainly be of great service.

The thoracic symptoms of grippe are extremely variable, and the most painful symptom, which was particularly observed during the last epidemic, is a convulsive cough which often gives rise to vomiting. The following prescription, which was recommended by Monin in cases of whooping-cough, has given rather good results: Tincture of belladonna, tincture of aconite, and tincture of drosera, each, 30 grains; tincture of myrrh, 150 grains. From twenty to thirty drops a day are to be taken in divided doses.

The congestion of the underlying structures often resembles that of typhoid fever, and, as in typhoid fever, it is combated by the lateral recumbent posture and the sitting posture. It is often indispensable to make the patient lie down for several hours a day on a couch. Daily dry cupping or, if necessary, wet cupping, in robust persons, should be practiced. Blisters are usually more harmful than useful. Tonics, coffee, cognac, and Todd's potion should be employed.

In cases of respiratory catarrh with abundant expectoration, an emetic is often useful for children and adults. Preparations of kermes and antimony may be carefully used. Forty-five grains of ammonium hydrochloride a day, given in six doses, is preferable to the former. In cases of nervous symptoms of an ataxic type, with agitation and delirium, potassium bromide is the best calmsative: it has no harmful, depressing influence if it is administered in small doses. From thirty to sixty grains a day may be given. Chloral is more efficacious in insomnia, but it sometimes increases the cough, which, however, is not so marked if a syrup of chloral containing a bromide is used. In addition to these medicines, cool compresses on the forehead and cooling lotions are indicated, and in obstinate forms heroic measures, such as a cold or a hot bath.

Adynamia is, in the nervous form, more frequent than ataxia. Here hygienic means, such as pure air, stimulating frictions over the entire body, inhalations of oxygen, coffee, champagne, and alcohol should be employed. Adynamia is sometimes so marked that Le Gendre, says M. Plaque, advises strychnine. Kola is also very efficacious in the nervous depression that manifests itself in certain forms of the disease. It may be given as a wine, as a tincture, in powders, or granulated. The latter form seems to contain the largest quantity of the active principles. If the tincture is used, it may be associated with equal parts of tincture of coca.

In the cardiac form, aside from external means, subcutaneous injections of caffeine and of ether may be resorted to. Injections of a hundred and fifty grains of sterilized olive oil and thirty grains of camphor are also productive of good results, given from once to three times a day. To the ordinary remedies for the adynamic symptoms tincture of digitalis may be added, and from twenty to thirty drops a day may be given in divided doses.

The gastro-intestinal form should be treated in the beginning with emetics in young persons and with saline purgatives in old persons. Frequent washing of the mouth with an alkaline water will diminish the sensation of puffedness and anorexia. For profuse diarrhoea intestinal antiseptics, such as salol, bismuth salicylate, and napthol, should be employed rather than opium, the action of which is always doubtful in infectious diseases.

In convalescence, often long and painful, hygienic treatment is especially indicated, and arsenic, cinchona, cocoa, kola, and sometimes iron are particularly indicated. In cases of neurasthenia and of persistent weakness, it should be ascertained if the phosphaturic albuminuria described by M. Albert Robin is present.
MINOR PARAGRAPHS.
THE ARCHIVES OF PEDIATRICS.

We learn that with the May number of this excellent journal the editorial control passes into the hands of Dr. Floyd M. Crandall, who for several years past has done good work as a member of our own staff. Our knowledge of this good work makes us confident that Dr. Crandall will conduct the Archives carefully and successfully.

Died.

Breintnall.—In Newark, N. J., on Monday, March 4th, Dr. John H. H. Breintnall, aged sixty years.

Hoadley.—At West Pond Beach, Fla., on Monday, February 25th, Dr. Frederick H. Hoadley, aged forty-five years.

Payne.—In Lexington, N. C., on Monday, February 25th, Dr. R. L. Payne, aged sixty-five years.

Vaughan.—In New York, on Monday, March 4th, Dr. Berhard E. Vaughan.

Letters to the Editor.

MALTSE VERSUS GLUCOSE.

SPRINGFIELD, MASS., December 28, 1894.

To the Editor of the New York Medical Journal:

Sir: It is with much pain and disappointment that I read that letter of Dr. R. G. Eccle’s in your issue of the 22d inst., purporting to be a reply to mine of the 8th. In my last letter I accused him of making one or two errors and an overstatement in his paper Maltose vs. Glucose, but now I charge him with eight or twelve errors in this letter. This is what I call redactus ad absurdum. I regret that he has shown a spirit of unfairness from the very beginning. He charges me with being liberal to myself in my interpretation of the words, when his statements are so bold and positive that they need no interpretation. Moreover, I did not adopt his tactics and assume that he said eight or nine different things that he never said at all, never making a quotation or intimating in any way on what the assumptions were based; whereas I reproduced his own words, so that each reader might judge for himself if I was justified in my statements. I only attacked the article at this one point, though I am free to say that that was not the only weak spot it contained. But then, I had no desire to be hypercritical. My criticism was made in good faith and should have received fair treatment at his hands. In this last letter he tells us that he “certainly never intended to say the things he charges me with.” Yes. But am I responsible if he said the things he never intended to say? That he did say them I will presently show by producing in parallel columns what he said in his paper and what he said in his letter. And I dare him to question the correctness of the quotations. If he did not mean what he said in the paper, as he says now, ergo the paper is valueless, and discussion is profitless and a waste of time, for how shall we know that he means what he now says? Why, then, write a letter of more than six hundred words, only about thirty-five of which have any necessary or logical connection with what I did say, while about five hundred are devoted to answering objection he assumes that I made, but which I neither made nor thought. Any one can dash off a flippant letter if he gives free rein to his imagination and let it, like a ship at sea, without rudder, chart, or compass, drift wherever it will, paying attention to no rules but those of the romancer. This is not the kind, however, which will enhance a man’s reputation for scientific accuracy. Of course, such letters read more smoothly and effectively and are better specimens of composition than
ones broken up by frequent quotations, and then their authors need not be so scrupulous about the correctness of their statements. If the doctor said what he did not mean, or if he inadequately described the meaning, there was an honorable way out of his dilemma—namely, to call it an error or an oversight, and acknowledge his obligation to Dr. Keefe for giving him an opportunity of putting himself correctly on record. The dear man could afford to do this much better than to descend to the arts of the quibbler; it would enhance his reputation as an investigator, a man like the late Professor Flint, large enough to acknowledge an error. He, however, preferred to follow the old maxim, common among the members of the legal fraternity,

"When you have no case, abuse the plaintiff's attorney."

It be remembered that I purposely refrained from expressing an opinion on a single point relating to digestion, only that the gastric juice can digest the gluten of bread, even though not previously acted upon by ptyalin or diastase, and that there is no such thing as a distinct layer of starch covering the gluten of bread and separating it from the gastric juice. I did not even say that disease would not follow the failure of the stomach to digest gluten. I only said that disease need not necessarily follow, and I told why by quoting Dr. Eccles. Any one can assure himself of this by referring to my letter. Yet, notwithstanding all this, he raises seven or eight points relating to digestion, deliberately chooses one side for himself and puts me on the other, and proceeds to demolish my arguments and condemn and executo me offhand. All this is very pleasant, no doubt, but a little one-sided, and hardly the love of truth and fairness to be expected of an investigator in so exact a science as chemistry. Let us now see how the doctor's statements made in his paper compare with those made in his letter, and for the better comparison we will arrange them in parallel columns.

What Dr. Eccles said in his letter:

"The ptyalin does not get mixed with the food, the starch is not digested from around the gluten, the pepsin can not do its work, and disease is the consequence."

As an artificial aid to digestion pepsin falls because it can not get at the gluten of the bread, because it is buried in starch.

Again, speaking of the stomach, he says: "All gluten reaches it enveloped in an insoluble coating, like the sugar or gelatin on the outside of a pill." This last is one I kept in reserve to contradict the denial which I expected, and which he has made in his letter.

Now, I should like to ask Dr. Eccles whether the statements made in his paper or those that appeared later in his letter are true; certainly both can not be. He can take whichever horn of the dilemma he likes. Verily, consistency, thou art a jewel. The doctor spoke of the last straw breaking the camel's back; if these parallel columns do not break the back of his reputation for accuracy of statement, then they will most certainly dislocate it. I will now briefly review a few more of his statements which I feel ought not to be allowed to go unchallenged. He thinks it impossible for authors to go into minute details of all their ideas. It is not only possible, but it is their bounden duty, especially those writing upon technical matters, to go into details, even to the extent of verbosity and tediousness, if necessary to have their ideas so clearly understood that there can be no question about them. The fact that nine authors out of ten do make themselves understood, shows that they do go into such details. He asks: "Can the doctor not see that even his meat, eggs, casein, etc., are buried in starch in the sense of my paper?" No, he can not see any such thing, for he never studied any rule in mathematics which said that the lesser was equal to or more than the greater, and among ordinary working and business people the consumption of the articles mentioned is about as great as that of bread, or even greater, so they could not very well be buried in starch. Nor can he see that insoluble and indigestible substances necessarily hinder the digestion of the soluble ones. This would undoubtedly obtain in a test-tube or glass vessel, where no movement of any kind was had, but in the stomach, where the relative position of solids and fluids is constantly changing, and where they are rubbed the one against and into the interstices of the other, it is a very different matter. Let any gentleman take any glass tumbler; put a teaspoonful, more or less, of sugar or salt into it. Let him now fill it half-full of pebbles, sand, or earth and then fill it with water and shake it, when he will find that, although the sand or pebbles are insoluble, they form no hindrance to the solubility of the sugar or salt. Although solution is not exactly synonymous with digestion, they are both practically hydrations. This is also illustrated by the fowl, which are found, when killed, with a stomach filled with pebbles, pieces of glass, etc.—in fact, the assortment is only limited by their ability to swallow. Still, it is popularly believed that they have the greatest capacity for digestion of anything in animate creation. Indeed, they are currently believed to be able to digest even shingle nails. I am quite sure that dyspepsia is not set down as a disease of the fowl tribe. Again, he says: "Will it be necessary to point out the fact to him that this difficulty, slight at first, becomes worse and worse the more the pepsin acts?" I would reply that it is unnecessary to point out the fact, for in my opinion there is no such fact. For, although, if the digestion were taking place, as I said before, in a vessel, without agitation, without churning or peristalsis, and without any provision for the removal of the products of digestion as it went along, then there would be some basis for the statement. When we remember that in the stomach not only are the alimentary matters changing places all the time, but the peptones are removed by absorption or by passing into the duodenum, in greater or less quantities as formed, but now gastric juice is constantly taking the place of that saturated. "Can Dr. Keefe not see the advantage of alternating modes of digestion, such as Nature has given us, or does he think all digesting to be done in a single place?" I never expressed an opinion on this subject, one way or another. I only expressed an opinion on the digestion of gluten. I did this, first, to avoid being hypercritical, second, for the sake of brevity, and, third, because, not being an expert on this subject, being only an ordinary general practitioner, I did not think my views of any great consequence. I will say now, however, that I do see the advantages of Nature's methods of digestion. The doctor continues "with the starch digested," etc. Yes, for, although I have not said pro or con in my previous letter, I will say by way of giving Dr. Eccles a grain of comfort, I think mystificating the food and thoroughly incorporating the saliva with it is a good thing to do. "Anything that hinders normal digestion, if for only ten minutes, must contribute to ten minutes' abnormal fermentation, and if it does not lead to disease, perhaps the doctor will tell us why." In the first place, let me remind my good
friend that I never said it would not. I simply said “disease need not necessarily follow.” Let me also call attention to his statement in this connection. He said: “The gluten is not digested, and disease is the consequence.” No, disease need not follow from delayed digestion of gluten—first, because gluten does not enter into fermentation, having neither starch nor sugar to support such a process; second, because its daily quantity, say, roughly speaking, twenty to fifty grammes, is by its softness, lack of bulk, and other unirritating qualities, not likely to irritate the stomach, much less to inflame it; but, lastly and principally, because the trypsin will digest it in the bowel. Regarding starch, although its digestion did not enter into the criticism I made, and has no place in it, I will say that the best authorities allow that in normal digestion starch is never completely digested in the stomach, no matter how much ptyalin, diastase, etc., we use. Hence the failure to digest the gluten would have no special effect on the stomach. It is certainly well to turn it over to the pancreatic fermentations when the action of the pepsin fails in consequence of its presence in the stomach. Who has said aught to the contrary? It is my opinion, however, that it does not fail from this cause alone. It seems to hurt Dr. Eccles’s feelings that I should have the temerity to quote Dalton’s, Physiology; he prefers Foster or Gamgee. Very good, there are medical colleges in this country, and good ones, too, that have this book down in their catalogue of 1894 as the preferred one in this branch. All a matter of taste, and, so long as he could not dispute the correctness of its dictum, it could make but very little matter. Moreover, I will say, just to mollify him, that I have since looked through Foster, Flint, Kirkes, and Yeo (Gamgee not being obtainable here), and find that, while two of them go more into details, they all agree on the question in dispute and on all the main facts of stomach digestion. Dr. Keefe does not believe that one or two engines will pull a train better than or even as well as three, and would like the word or sentence pointed out on which that statement is founded. In closing, the doctor makes a feeble attempt at imitating me, but he is obliged to resort to the unfairness that is characteristic of his whole letter, for he seeks to convey the impression that I called pancreatic juice pancreatin, whereas that word is not used in my letter at all, and, furthermore, the sentence has no relation to the matter in hand, being entirely meaningless. His wish that I be first correct and then consistent, is, I am happy to be able to assure him, a fait accompli, and I challenge him to point out an error or an inconsistency. In conclusion, I urge that he read my last letter anew.

Daniel E. Keefe, M.D.

Proceedings of Societies.

PHILADELPHIA ACADEMY OF SURGERY.

Meeting of January 7, 1895.

The President, Dr. William Hunt, in the Chair.

The Indications and Nature of Treatment in Severe Abdominal Injuries and Intra-abdominal Hæmorrhages Unaccompanied by External Evidence of Violence.—Dr. John B. Deaver read a paper on this subject, which was, he said, one that must appeal to every practical surgeon.

Every surgeon had undoubtedly, at some time in his experience, either in private or hospital practice, met with cases coming under the class covered by the title of this paper. These were cases in which the history and general condition of the patient gave the impression that there was a serious lesion within the abdomen, and yet, upon examination, we found total absence or only slight evidences of injury. The tendency, he feared with many, was to treat these patients tentatively, only to be awakened at the autopsy to the fact that a rupture or a tear had existed in the abdominal cavity, which, by early radical operation, could have been relieved.

The mortality in these cases was appalling; references to the literature of the subject would amply bear out this statement, which was rarely accounted for by the nature of the injuries. Where the lesion was of the liver or the spleen, if the patient did not die of shock or haemorrhage, a violent peritonitis supervened to which he shortly succumbed. If the liver, the spleen, or the kidneys were involved, death from haemorrhage might ensue in a very short time. Should the stomach, the intestine, or the bladder be ruptured and its contents poured into the peritoneal cavity, death from peritonitis was the result. In rupture of the mesentery the danger was from haemorrhage, yet, when the opening in the mesentery was small, a clot might form sufficiently large to control the bleeding. Should death occur under these circumstances it would be the result of peritonitis caused by the free blood in the peritoneal cavity. Dr. Deaver reported a case of this character where recovery had followed immediate operation. In ruptured extra-uterine gestation sae’s death was due either to haemorrhage or to peritonitis.

The usual history of these cases, with the exception of extra-uterine pregnancy, was that the patient had received a direct injury to the abdomen, which was found to be unaccompanied by external evidence. These injuries might result from railroad accidents, from being caught between shifting cars, or from blows upon the abdomen received in various ways.

This class of injuries was quite common in military surgery, more so in the past when spherical balls had been used and only a low velocity attained. A majority had been supposed to be caused by the violence of the wind displaced by the passing ball, but we now knew that they had been due to the impact of the balls almost entirely spent.

Two cases which illustrated this had occurred at the siege of Sebastopol. In neither had the clothing or the abdominal walls shown any signs of injury, but in both the liver and spleen had been comminuted to a pulp, and the intestines extensively lacerated (Mr. Hulke, Lancet, December 31, 1892).

As yet we had no reports from surgeons of the armies engaged in the present strife between Japan and China, but it would be of great interest to read the records of such cases. We could expect, he thought, a very full and detailed account from the Japanese surgeons. We had all applauded the work of some brilliant individuals of the Japanese profession, and, in fact, we must assign to Japan in medicine the same standing that she had taken in other walks of civilized life, and which she had demonstrated she could hold.

The most prominent symptom was pain, which was accompanied by shock, the degree of which was dependent upon the extent of the injury and the temperament of the individual.

Dr. Deaver thought that temperament and nationality had a strong bearing in the production of shock. Persons of a highly nervous temperament suffered more from shock than phlegmatic individuals did. For example, Americans were far more apt to suffer a severe degree of shock following injuries or operations than the Germans were.

The pain was peculiar and difficult to describe, but was readily recognized by one who had seen many of these cases and by the patient himself. It was not that of ordinary intra-abdominal affections, but was described by the patient as if something had given way or ruptured, and was usually accom-
panied by a consciousness of impending death, also with tenderness, which would be more or less localized, unless the causing peritonitis was general. In the early stages of the injury, when shock was most profound, it might not be so pronounced, and if large doses of opium were administered it might be masked throughout the course of the trouble. When vomiting was present it was usually associated with pain. Rarely did the vomited matter contain blood. There was often seen a characteristic rigidity of the abdominal walls, which was due to intra-abdominal irritation. He had seen this so marked as to recall to mind the check-board appearance of the normal abdominal walls as represented in the pictures of the early artists. In the cases he had observed, consciousness had invariably been retained for varying periods of time. Restlessness was not usual in the early stages except in severe haemorrhage, but later on, when peritonitis developed, it was not an uncommon symptom.

The pulse and temperature varied according to the degree of shock. The former was weak and varied from 100 to 106, and the temperature was subnormal. If reaction took place the pulse became stronger and less frequent, and the temperature reached the normal line. After reaction peritonitis was invariably the rule, and was accompanied by an accelerated and high-tension pulse. The temperature under these circumstances was unreliable, as it did not correspond to the degree of inflammation or septic infection. A high temperature with a slow pulse was less significant than a rapid pulse with a low temperature. In cases of septic peritonitis where an autopsy had subsequently revealed a belly cavity full of foul pus, he had seen the temperature run a normal course throughout the disease.

The part that the sympathetic system of nerves, which had its largest distribution in the abdominal cavity, might play in injury to the abdomen was important in considering the diagnosis between simple contusion and contusion accompanied by visceral lesion. In the former the absence of the severe and characteristic pain, of constant and persistent vomiting, of the chronic expression and presentiment of impending death, and of any evidence of loss of blood, associated with the occasional presence of suddenly developed meteorism, would usually be sufficient to establish the diagnosis. This condition of meteorism was due to paralysis of the muscular coat of the bowel consequent upon the concussion of the peritoneum. There were cases, however, where it was very difficult to say definitely whether there was a visceral complication or not. Under these circumstances one could only wait for a comparatively few hours, when, if improvement was not apparent, the operative course was to be pursued. When the solid viscera were the seat of injury haemorrhage would be the main source of anxiety. The pain and the exsanguination gave the clue. If the patient should react, which was unusual, unless the kidney was the injured organ, we should find, in addition, dullness on percussion in the flank. Rectal or vaginal examination might afford aid in determining the presence of a collection of blood in the pelvis. The solid organs suffered most from external violence, on account of their fixity, their density, and their close proximity to the bony structures. The liver was the most often injured, then the uterus, the spleen, and the kidney, in the order named. The stomach was least often injured, there being very few such cases on record. Dr. J. W. Goff, in the Medical and Surgical Reporter, 1892, had reported a case of ruptured stomach following a horse kick of the abdomen, verified by an autopsy. The shock had been profound, and there had been vomiting with absence of blood. The author stated that he believed an immediate operation would have saved the patient's life.

In the Glasgow Medical Journal for 1894, vol. xli, Andrews had reported a case of rupture of the stomach without external evidence of violence, in which all the symptoms of a serious visceral lesion had been present with the exception of vomiting. The rupture had been upon the anterior wall; it had been about an inch long, and had involved all the layers. The speaker cited this case as one of special interest on account of the location of the tear and the absence of vomiting.

The liver was the organ most often affected, because of its position beneath the ribs and against the spine, and because it was held firmly in place by strong ligaments and blood-vessels. It was most commonly ruptured on its upper surface, generally in the right lobe, and in a majority of such cases the injury proved fatal. Dr. H. P. Loomis, in the Medical Record, had reported a case where the patient had been struck by a pole protruding from the back of a wagon, which, when the wagon turned the corner, had struck him on the right side, leaving no external evidence of violence. There had been a three-inch tear in the right lobe of the liver and a pint of blood in the abdominal cavity. The patient had died in the street from haemorrhage before medical aid could reach him.

Mr. Battle, in the Lancet, 1894, had reported a case of rupture of the bile duct in a boy six years of age who had been run over by a hansom cab. There had been but slight shock without much pain or tenderness. Vomiting had begun early and had persisted. On the fifth day slight jaundice had developed. He had been operated upon on the eighth day, and the abdominal cavity had been found filled with bile. He had died on the morning of the ninth day.

At the autopsy the liver and the gall-bladder had been found intact, but about half an inch beyond the junction of the cystic and hepatic ducts the common duct had been found torn completely through. No other injury had been found.

The cases reported by Dr. Deaver were as follows: J. E., aged forty-six years, had been admitted into the German Hospital on November 17, 1893, suffering from injuries received by being struck by a locomotive. He had had a compound fracture of the lower jaw, lacerated scalp wound, and a fracture of four ribs on the left side, with no other signs of injury. He had died six hours later. The post-mortem examination had revealed a haematotherax of the left side. The peritonaeum had not been perforated or otherwise injured, but the peritoneal cavity had been filled with blood. The spleen had been completely comminuted, and the left kidney had been forced from its bed and was floating in the retroperitoneal space. There had been an extensive haemorrhage between the layers of the mesentery, and a haemorrhagic extravasation of the posterior wall of the stomach.

H. M. C., colored, aged sixteen years, had been admitted into the German Hospital on the evening of December 3, 1894, with the following history: While playing about some moving freight cars he had been accidentally caught between the bumpers, sustaining an injury to his abdomen. An examination upon his admission had failed to disclose any evidences of external injury. The introduction of the catheter had drawn clear urine. There had been a moderate degree of shock, and the patient had complained of severe pain in the abdomen and tenderness on palpation. Further investigation had proved negative.

The resident surgeon, Dr. Page, not having deemed the case of sufficient severity to send for the speaker, had treated the patient for shock. When Dr. Deaver examined him, upon the following day, it had been very evident, from the severity of the abdominal pain and tenderness associated with very decided rigidity of the abdominal walls, that he was suffering from a serious intraperitoneal lesion. He had decided to open the abdomen at once. As soon as the peritoneal cavity had been opened a large quantity of dark liquid blood had escaped. The small intestines had been drawn out, when the cause of the
lesion had been found to be a ruptured mesenteric vein, the bleeding from which had been arrested by the presence of a large diffused blood clot occupying the interval between the layers of the mesentery. To make sure that there had been no other lesion, the large intestines, the stomach, the liver, and the spleen had been carefully examined, but with a negative result. The abdominal cavity had been washed out with warm saline solution, a glass drainage-tube had been introduced into the pelvis, and the wound had been closed. Recovery had been uninterrupted.

L. C., an Italian, aged thirty-five years, had been admitted into the German Hospital with a history of a fall of about fifty feet, striking upon his abdomen. He had been profoundly shocked and exsanguinated. The only external evidences of injury had been some slight cuts on the hands and head. A diagnosis of internal hemorrhage had been made, and the abdominal cavity opened. Dark liquid blood had escaped as soon as the peritoneum had been opened, and the source had been found to be the mesenteric vessels. The mesentery had been torn half-way across and the intestines lacerated in four places. The mesentery had been united with a series of catgut ligatures. The rents in the intestines had been closed with the Lembert sutures. The abdominal cavity had been washed out with hot saline solution and then closed. The man had died two hours after the operation. The autopsy had demonstrated several tears in the gut which had been overlooked, and several grape-skins and pieces of lig in the peritoneal cavity.

The commonest form of intra-abdominal hemorrhage was that resulting from a ruptured extra-uterine gestation-sac. While the rupture might be due to traumatism without any external evidence, it was usually spontaneous. While hemorrhage from the pelvic organs of the female usually occurred from a ruptured extra-uterine gestation-sac, it might be due to other non-traumatic causes. Hematosalpinx might occur independently of pregnancy, and rupture either spontaneously or from traumatism. Again, degenerated blood-vessel walls, and especially veins, might rupture under similar circumstances.

M. E., aged twenty-four years, a nurse, had been admitted into the German Hospital on January 20, 1893. While lifting a heavy weight from an elevator she had felt something give way in her abdomen. This had immediately been followed by severe lancinating pain in the right ovarian region. She had been menstruating at the time. Pelvic peritonitis had promptly set in. An examination had demonstrated a tumor in the right broad ligament of about the size of a hen's egg. The peritonitis and tumor had subsided under treatment, and she had made a slow recovery. The diagnosis had been pelvic hematocele from rupture of an engorged ovarian vein.

Haemorrhage itself was seldom the cause of death, but, associated as it was with shock, the degree of which was out of all proportion to the severity of the accident, it was frequently fatal in a very short time. When the peritoneum was wounded shock was still more profound—the so-called peritoneal shock.

Haemorrhage within the peritoneum was sometimes very slight and distinctly localized, and might occur several times during the course of the illness. It might take place between the layers of the broad ligament, and soon stop from the pressure.

Dr. Deaver reported the two following cases of hemorrhage from his list of operations for ruptured extra-uterine gestation-sae, as they illustrated so typically, he said, the wisdom of an immediate operation:

Mrs. A. K., aged thirty-one years, had been admitted into the German Hospital on September 21, 1894, with the following history: Six months prior to her admission she had been subject to attacks of vertigo and pain in the back and limbs, and for the last six weeks to a constant bloody vaginal discharge. Examination had revealed a retroflexed uterus with a slight tear of the cervix and the presence of a small movable mass behind and to the left of the uterus.

On September 25th, four days after her admission, the patient had been etherized, and the uterus had been dilated and evacuated. After the operation the discharge had stopped, but the patient had gained in strength very slowly. She had been advised to submit to abdominal section, but had preferred to wait until she was stronger. On the night of November 24th she had awakened with a severe pain in the right side, and on attempting to walk to the water-closet had fainted. After having been returned to bed she had again fainted and gone into collapse, the pulse becoming almost imperceptible and the temperature falling to 96°. Under active stimulation she had reacted. The diagnosis had been made of internal hemorrhage from rupture of a probable extra-uterine gestation-sac.

The abdominal cavity had been found filled with fluid blood and clots, and the right tube had been ruptured. The tube had been tied off and the abdominal cavity flushed with hot saline solution, a glass drainage-tube had been introduced and the wound closed. The patient had not been much shocked by the operation, but, on the contrary, had seemed rather improved. The drainage-tube had been removed on the third day, the wound had healed by first intention, and the patient had made a good recovery.

Mrs. J. W., aged thirty-six years, had been admitted into the German Hospital on November 21, 1894, with the following history: About two o'clock on the morning of her admission she had been seized with a violent pain in the lower abdomen. For this she had taken some whisky, and had been somewhat relieved. At nine o'clock the same morning she had started for market, and had suddenly been taken sick, becoming very weak and suffering from a violent pain in her abdomen. She had returned home with difficulty and had called in Dr. Hand, who had advised her immediate removal to the hospital. At the time of her admission she had been very weak, and there had been distinct tenderness over the abdomen with slight dulness on the right side. An immediate operation had been advised and consented to.

When the peritoneal cavity had been opened it had been found to contain fluid blood and clots. The right tube had been the site of a small rupture, and had been tied off and removed. The abdominal cavity had been washed out with hot saline solution, a glass drainage-tube had been introduced, and the wound had been closed. The patient had been very much shocked by the operation and had reacted slowly. During the operation hypodermatoclysis had been practiced. The drainage-tube had been removed on the fourth day, the wound had healed by first intention, and the patient had been discharged, well, on the twenty-third day.

The following case of hemorrhage from ruptured extra-uterine gestation-sac, the speaker said, illustrated the danger of delay as strongly as the two previous cases did the efficacy of prompt interference:

Mrs. P., aged thirty years, had been a patient of Dr. S. Cooke Ingraham, of Wissahickon, who had furnished the following history:

Dr. Ingraham had first seen the patient on January 29, 1892. She had complained of severe abdominal pains of a bearing-down character, and of a sense of fullness in the epigastric region. She had been married seven years, but had never been pregnant, and had laughed at the possibility. For the past three years the menstrual flow had been decreasing in amount, and for several months past it had been very scant. The breasts had been slightly enlarged, but the areolae had not been dark-
The glands of Montgomery had been a little more prominent than normal. She had suffered from morning vomiting for a month before.

He had been hastily summoned to see the patient on the morning of February 2d, and had found her in a state of collapse, pulseless, and with a temperature of 96° F. She had reacted to active stimulation and had been sent to the German Hospital for immediate operation, where a diagnosis of ruptured extra-uterine gestation-sac of the tubal variety had been made. Upon her admission, her pulse and temperature had been normal. She had not complained of pain. Examination by the abdomen and per vaginam and per rectum had failed to reveal any mass, although a circumscribed area of flatness could be demonstrated low down and to the right side. She had continued in this condition until February 12th, when at her own request she had been discharged. On February 23d she had been readmitted at Dr. Ingraham's earnest request. At the time of the second admission the abdomen had been markedly distended, being tympanitic above and flat below. Pulse 116, temperature 101° F. She had complained of considerable pain.

On the following day she had been operated on, and when the peritoneum had been opened a uterus with clots and fresh blood had gushed out. The ruptured sac had occupied the right iliac region, and had been tightly adherent to the neighboring coils of small intestine, to the omentum, and to the veriform appendix. After a prolonged and tedious dissection the sac had been enucleated; this had been accompanied by very free bleeding, which had made it necessary to pack the cavity with gauze. The wound had been closed with the gauze packing in situ. The patient had died on the following day of hemorraghe.

The immediate effects of an injury, said Dr. Beaver, severe enough to cause a serious lesion of an abdominal viscus were sometimes so slight as to be misleading. Very often a patient with such a condition would walk to a conveyance or to the hospital, complaining only of a slight pain. In varying periods of time following the injury more decided symptoms would develop—viz., signs of hemorraghe if the solid organs were involved, and early peritonitis if the hollow visera were ruptured or torn sufficiently to allow their contents to escape. When this occurred an operation was imperatively demanded without delay. This was also true of hemorraghe consequent upon the rupture of an extra-uterine gestation-sac, traumatic or spontaneous. In ectopic gestation an operation would be necessary in every case at some period of its history; therefore, if a diagnosis could be made, or even a well-founded suspicion of the condition existed, rupture should not be allowed to occur. If rupture did occur, however, immediate interference was the only certain means of saving the patient's life. The longer the operation was deferred, the greater the risk to life. Hasty operations, often made necessary by the patient's condition, were likewise less likely to reach a favorable termination. Blood clots or intestinal or gastric contents could not be washed out of the peritoneal cavity except by prolonged and repeated flushing.

The almost invariable fatality of intra-abdominal lesions of traumatic origin was so well recognized that it seemed as if there could hardly be any question as to the wisdom of opening the abdominal cavity. He would not be understood as meaning that abdominal section should be used as a means of diagnosis, but, on the contrary, he believed that every known means, with attention to the most minute details, should be exhausted in establishing a diagnosis. When a diagnosis was impossible abdominal section was justifiable only when it became the last and only chance for the patient.

He had refrained from using the terms exploratory and diagnostic incisions, believing that they not infrequently served as a shield to cover a lack of diagnostic ability. It was a moral obligation resting upon every physician and surgeon to develop to the utmost of his ability the highest diagnostic attainments. Aseptic surgery, said the speaker, had undoubtedly been one of the greatest boons to humanity that this nineteenth century had brought forth. But he thought that it afforded a great temptation to men who had not had experience and surgical training, and who had, therefore, not fully developed their diagnostic skill, to do operations which were not necessary for their patients' good, and to do them without scientific precision.

**Book Notices.**

The author takes as his text Bouteille’s eighty-year-old criticism: *Tout est extraordinaire dans cette maladie; son nom est ridicule, ses symptomes singuliers, son caractere epique, sa cause inconnue, son traitement problematique.* This is elaborated in the statement that in “the whole range of medical terminology there is no such ollo podrida as chorea, which for a century has served as a sort of nosological pot into which authors have cast indiscriminately affections characterized by irregular, purposeless movements.” Reference is made to the fact that the epidemic disorder of motion that Paracelsus called chorea Sancti Vitii has a sort of prescriptive right to the name, while two centuries of usage have conferred Sydenham’s error in adopting it for an affection of a totally different nature.

In order to make a classification, the author groups these various affections into chorea major, that includes the dancing mania and the various forms of rhythmic or hysterical motor disturbances, chorea minor, or Sydenham’s chorea, choreiform affections, or pseudo-choraeas, that include the various forms of localized or generalized habit spasms, and secondary or symptomatic choraeas, that are chronic disorders of motion that depend upon degenerative and irritative lesions of the motor cortex or tract. Chorea major and symptomatic chorea, except Huntington’s chorea, are not considered in the book.

The author briefly surveys the history of the disease and then gives its general etiology. He finds that seventy per cent. of the cases occur in females, and the incidence of the disease is earlier in them than in males. In the second quinquennium of life the greatest number of cases occur in males, and in the third the greatest in females. The disease more commonly affects children of the artisan and lower classes. Lewis’s conclusions as to the seasonal relationship of chorea and rheumatism are adopted. Dr. Osler thinks that there is a tendency to the disease in certain families, and that temperament plays an important predisposing rôle. In the section on psychological influence there is an error in the statement that “the strain of education, particularly in young girls, during the third decade, is an important factor”; presumably the author intended, to use his phrase, “hemidecade” or quinquennium. The author does not place much value on the imitation theory regarding the etiology of the disease, but believes that endemics attributed to that cause are hysterical motor disorders rather than true chorea minor. And he does not attach much importance to reflex irritation as a causative factor. He has found rheumatism associated with chorea in only 15.5 per cent. of a series of 554 cases.
The symptoms of the mild, severe, and maniacal forms of chorea, the motor disturbances, the phases of muscular weakness, and the sensory and cutaneous disturbances are described. A separate chapter is devoted to the heart in chorea minor. Professor Osler states that it is exceptional to find the heart healthy in chorea, and that in no known disease is endocarditis so constantly found post mortem as in chorea. This latter statement seems remarkable in view of the frequency of endocardial complications in acute rheumatism. In a total of 1,144 cases of chorea, 28.4 per cent. presented cardiac murmurs. The author states that these murmurs may be functional or organic, but it seems to the reviewer that the functional murmur is more frequently encountered, and is, as the author says, usually due to debility and rheumatism. Taking his own and Sturgess's collected cases, a total of 153 fatal cases of chorea, a normal heart was found in only 14.5 per cent., while in a single collection of 45 fatal cases of rheumatic fever 17.7 per cent. of the subjects had normal hearts."

The author again refers to his published investigation of 140 persons examined two or more years subsequent to the attack of chorea, of whom 51.4 per cent. had organic heart lesion. Of these, 25, or 34.1 per cent., had a history of acute arthritis, and this has materially increased the percentage. Deduct these 25 cases from the total and from the total affected, making 115 for the one and 47 for the other, and the percentage of cases of organic heart disease following chorea becomes 40.8 per cent., still a high ratio. Dr. Osler considers that in the majority of cases of chorea minor complicated with endocarditis the heart trouble is independent of acute arthritis, and not associated with it, unless, indeed, the valvular lesion is to be regarded as a manifestation of the rheumatism. As Bonilhans says, chez les jeunes sujets le cœur se comporte comme une articulation.

Our present knowledge of the pathology of chorea is reviewed, and a comparison drawn between the features of that disease and those of rheumatism. Most observers will agree with the author that, we are as yet upon the threshold of our knowledge of the essential cause of either acute rheumatism or chorea; facts suggest an infectious origin of both diseases. Osler considers that the cause of chorea will be found to be a poison allied to that of rheumatism, but not identical with it. The section on treatment simply reviews current knowledge. A chapter is devoted to a brief review of choreiform affections, and the final chapter give an excellent résumé of our knowledge of Huntington's chorea.

There is an appendix giving an analysis of seventy-three fatal cases of chorea minor.

The book is written in the author's usual attractive style, and it is likely to give a good and definite idea of our present knowledge of this interesting disorder.

He states further that he has not considered ophthalmology, gynecology, rhinology, otology, and laryngology in this volume, because in the advanced state of specialized science only the specialist is competent to write upon these branches. Though these are not mentioned, the first chapter of the book is devoted to bacteriology, which is certainly as much a special science as the surgical features of any of the above-mentioned specialties.

The author is to be commended for his reference to the latest measures; for example, he advises the use of tetanus antitoxine in the treatment of tetanus, of modified tuberculin in the treatment of tubercular lesions, and of the Pasteur treatment for rabies.

In the description of the introduction of Bellocq's cannabis it might be suggested that the operator should first thread the eye of the stylet with silk that may be easily caught and drawn through the nose into the mouth, whereas an effort to thread the eye while it is within the mouth, and usually covered with blood, is a toilsome matter for both the operator and patient.

A close examination of the volume will show that it is essentially practical in its scope, judicious in its advice, and likely to prove of value to the student.

The appearance of a third edition of this work within two years indicates that it has received that favorable consideration that in our review of the first edition we said it was entitled to.

The author has not changed the lines on which he planned the book, and it is full of useful information for the student.

We would suggest that the administration of the thyroid gland as a remedial measure in the treatment of myxedema rests on a more certain platform of clinical data than might be imagined from the author's text; and that in the next edition of the work it might be well to state that the diagnosis of diphtheria is now generally held to depend upon the discovery of the Klebs-Löffler bacillus in the discharge from the respiratory passages.

The present edition of this well-known book gives evidence of careful revision, and the author has had the services of several well-known sanitary experts to prepare special sections.

Surgeon-General Walter Wyman and Passed Assistant Surgeon H. D. Geddings, of the Marine-Hospital Service, have contributed a very complete article on quarantine that embraces the latest features of this subject.

Medical Director A. L. Gilon, of the navy, has again revised the chapter on marine hygiene, and Dr. Seneac Egbert has revised the chapter on vital statistics.

While the work does not purport to have the completeness or comprehensiveness of some text-books on hygiene, yet it is sufficiently complete to furnish the groundwork for a knowledge of this important subject.

In the new edition of this popular manual the author has rearranged and rewritten the part relating to the carbon compounds, reclassified the alkaloids, and made some references to the ptomaines and lecucamines, thus making the volume as likely to prove serviceable in the future as it has proved itself useful in the past.

The author has taken occasion in the preparation of this new edition of his manual to thoroughly revise his text, and the value of the book is now enhanced by the introduction of some fifteen half-tone illustrations. The included matter has been carefully selected and the volume is likely to prove useful to students.

In the first chapter of this work, devoted to blood serum therapy, the author states that the principles of the method are based upon the discoveries of Professor Behring, of Berlin, that the blood serum of an animal organism which has been rendered proof against a certain infectious disease has the power, when injected into another living organism, of protecting the latter against the disease and even to cure it after infection. As a matter of fact, Behring did not make this discovery, because Riehet and Héricourt first demonstrated the principle in regard to staphylococcus infection, and Professor V. Babes had established it in regard to rabies, while Kitsato must be given equal credit with Behring for the work done to prove the protective power of the tetanus antitoxine.

The second chapter considers toxins and toxalbumins in an interesting review of the characteristics of those substances. The last two chapters are devoted to tetanus and diphtheria respectively, and describe the effects and methods of production of the toxins and the antitoxines of each of these diseases.

The volume is illustrated with seven plates representing the principal varieties of pathogenic micro-organisms, and it is worth the perusal of those desiring information regarding the important subject of which it treats.

This is a concise and practical handbook for use in the bacteriological laboratory, intended to save the student's time by giving him just such data as he needs to make an examination for bacteria in general, or for any special form of micro-organism. As the author says, no single text-book describes all the methods enumerated in this opusculum. The size of the work permits of its easy use at the laboratory table.

Bacteriological technique in general is briefly referred to, the methods of staining bacteria in cover-glass preparations and in sections are described, and the various special stains for particular micro-organisms are mentioned in detail. Short sections on preparations of nutrient media and on embedding tissues for cutting sections complete the work.

We believe that students of bacteriology will fully appreciate the author's ingenious plan.

That this work has passed through three editions in Germany is an evidence of its usefulness, for it was first published as an appendix to Ziegler's General and Special Pathological Anatomy and subsequently in a separate form. We agree with Dr. Sims Woodhead that the translator has conferred a boon on the busy student of morbid histology in acquainting him with the many useful methods described by von Kahlden.

The various chapters describe the microscope and the apparatus requisite for histological work, the methods of examination of fresh tissue, of hardening and decalcifying tissue, of embedding, of injecting tissues, of making and mounting sections, of staining, of examining degenerated tissues, and of examining bacteria, molds, and animal parasites, while the last two chapters describe the detail of microscopical examination of special tissues and organs and of examinations made for medico-legal purposes.

The volume deserves a wide popularity among students in American colleges.

Whatever Mr. Burdett does he does well, and this work must be of use to many classes in a community. It is, he states, a second edition of his smaller manuals, Helps in Sickness and Helps to Health, which have been rewritten so as to combine them in one volume.

In these pages he has included the main principles of hygiene, the essentials of first aid to the ailing and injured, and a directory of institutions in England and Wales founded for the relief of sickness or bodily infirmity.

The first part of this work, Helps to Health, gives information regarding the arrangement of the nursery, the school, the care of the person, food and drink, exercise and refreshment, the choice, structure, and arrangement of a house, and the sanitary powers and duties of the citizen. Much useful knowledge is included in the portion devoted to the arrangement of the house, and the book is so written that one with the most elementary knowledge may easily understand it.

In the second part the treatment and nursing of emergencies and slight ailments is considered at sufficient length to afford much useful assistance to those who await the physician's coming. The chapter on infection and disinfection is likely to prove very suggestive to any one who has had a case of infectious disease in his home.
BOOK NOTICES.—MISCELLANY.  

There is a short chapter on sick-room cookery and food. The third part gives full particulars of the terms of entrance, and hours of attendance and admission, of all institutions in England and Wales founded for the relief of sickness or bodily infirmity. The volume is a timely contribution to the popular literature of hygiene.

Miscellany.

Beri-beri due to Decomposing Fish.—At the last meeting of the American Climatological Society Dr. Judson Dulan, of Philadelphia, reported three interesting cases, and he has recently had the privilege to furnish us with the report in the form of advance sheets of the society’s Transactions. With some omissions, it reads as follows:

The first case occurred in a married man, aged forty years, a native of Port Said, Suez. He states that his wife and family are in good health. When first seen by Dr. Henry C. Boening, to whom kindness I am indebted for the privilege of making this report, the patient lived in Philadelphia, and that was considered cardiac palpitation. The systolic murmur is now most distinct over the third left intercostal space, and a fine diastolic murmur can be heard, especially in the fifth intercostal space to the right of the sternum. On November 16th the heart was acting regularly, and the diastolic murmur was heard, having its point of maximum density over the tricuspid region. Later these murmurs disappeared. Emmaculation was rapid; there were epigastric tenderness, muscular soreness, slight oedema of the legs and splenic region. On admission to the Quarantine Hospital the lips and face were absolutely anaesthetic, and the former could be transfixed with a needle without producing the slightest pain. Six days later intense hyperesthesia developed in these regions, and the patient could not tolerate the contact of a spoon to the lips. The hands and feet were anaesthetic. The musculature was unusually developed, but there was no loss of power. He could flex the toes, but could not extend them. His reflexes were diminished. Remberg’s symptom was absent, and the urine was normal.

Sixteen days afterward I made an examination of the blood, with the following result: The color, consistence, and coagulability of the blood appeared normal as it exuded from the puncture. The red corpuscles were normal in size, showed no myocytes, megalocytes, nor poikilocytes. The Thoma-Zeiss hemocytometer was employed in counting the red blood-cells, which numbered 4,750,000, or ninety-five per cent., and Fleischl’s hemometer
March 9, 1895.]—

MISCELLANY.

317

gave sixty-five per cent. hemoglobin. There was a moderate
grade of leucocytosis, and the white corpuscles numbered about
80,000 to the cubic millimetre. Many were remarkable for
their gigantic size, and contained large coarse granules, not un-
like the eosinophile cells that are found in such numbers in the
blood of leucæmia. Blood plaques were present in moderate
numbers. Careful search was made for the plasmodium of ma-
laria, filaria, and micro-organisms, but none was discovered.
As the corpuscular value of this blood was ninety-five per cent.,
and the hemoglobin value but sixty-five per cent., each corpus-
ucle contained two thirds the normal quantity of hemoglobin.
At this date there was again an alteration in his cutaneous sen-
sibility. There was complete anaesthesia of the nasal and aural
mucous membranes, as well as of the entire skin, with the ex-
ception of the deltoid regions, following more or less closely
the origin of this muscle, and the left inferior axillary region,
where there was an area of normal sensation covering five by
two inches and a half. The knee-jerk was slightly exagger-
ated, and careful examination of the viscera gave negative re-

The second case was that of a man aged twenty-one years.
He was admitted to the Lazaretto on November 11th, and the
following is the result of Dr. Boenning’s examination at that
time:

Decidedly weak, legs very oedematous, intense dyspnoea,
a double cardiac murmur, irregular heart, pulsating jugulars,
throbbing carotids, extensive nerve disturbances, and diarrhoea.
Two days after admission this man exhibited a sudden serious
efusion into the tunica vaginalis. He also became anacorous
and very short of breath. A physical examination showed pul-
monary oedema, a marked enlargement of the cardiac dulness,
irregular ventricular action, a strong but low-pitched mitral mur-
mur, a very well marked tricuspid murmur, a well-defined thrill
over the precordia, and pulsation of the external jugulars. His
neck was somewhat edematous. He had a cough, and occasion-
ally expectorated frothy mucus slightly tinged with blood.
In this case there was irregularity in the time of the contraction
of the auricles and ventricles. The nerve disturbance was marked.
There was anaesthesia of the upper lip; the lower lip was hyper-
aesthetic. The right upper extremity presented small areas of
anaesthesia; the skin over the entire left upper extremity was
devoid of sensation. There was an entire loss of the tactile
sense. The abdomen was hyperaesthetic. The skin along the
inner side of the thighs and anterior and outer side of the legs
was anaesthetic, but a very deep puncture (half an inch) was
felt. There was an entire loss of reflexes, including the cutane-
ous of the sole and palmar. On November 27th I examined the blood, and found that, as
it exuded from the incision, it seemed rather more fluid and
paler than normal. Its coagulability was unchanged, but the
red corpuscles were of great variety as regards size. A few
were larger than normal, and many were only half the diameter
of a normal red cell.

There was a moderate number of microcytes, but there was
no tendency to poikilocytosis. The Thoma-Zeiss hemocytom-
eter showed that there were 4,400,000 red corpuscles to the
cube millimetre, or eighty-eight per cent., and a careful count of
the microcytes showed that there were 400,000 to the cube
millimetre. In counting the microcytes, all red cells having a
diameter of one half or less than the normal diameter for red
blood-corpuscles were counted as microcytes.

Many of these were mere round points, but their true char-
acter was made clear by the color given them by the hemog-
lbin present.

There was a moderate grade of leucocytosis, the white cor-
puscles numbering about 40,000. They, too, varied in shape,
some being as small as microcytes, and many of them were
corealy granular, resembling eosinophile cells. As the cor-

pusscular value of this blood was eighty-eight per cent., and
the hemoglobin value but sixty per cent., each cell contained but
three fourths of the normal quantity of hemoglobin; but, as
400,000 of these red globules in each cubic millimetre were mi-

rscytes, it is plainly evident that each blood-cell contained ap-
proximately its normal quantity of hemoglobin. As many of
these microcytes were mere round points in size, it is evident
that the oxidizing power of the blood was considerably reduced,
and it is safe to assume that there was an actual loss of forty
per cent. of hemoglobin.

Search was made for the plasmodium of malaria, filaria, and
micro-organisms, but none were discovered. His sensory symp-
toms were as follows: The numbness of which he complained
originally had entirely disappeared. There was complete anes-
thesia of the nasal and buccal mucous membranes, the palms of
the hands and soles of the feet and the entire skin surface, with
the exception of an area three inches and a half wide in the
infra-axillary region, extending from the anterior axillary line
to the vertebral column. There was no knee-jerk, and the cre-
masteric and abdominal reflexes were absent; the papillary re-
flex was normal. Respirations were twenty to the minute, and
the hungs were normal. The apex-beat of the heart was diffused,
occupying an area of at least two inches and a half in diameter
around the normal apex region, and was plainly felt in the fifth
interspace a trifle within the nipple line.

The impulse was more forcible than normal, was regular,
and there was no thrill. The area of cardiac dulness was not
increased. The first sound of the heart was heavy and muscu-
lar, like that of simple hypertrophy, and was accompanied by a
moderately long, rather harsh, blowing systolic murmur, which
was transmitted into the axilla, and was also carried over to the
right border of the sternum on a level with the fifth interspace.
At the pulmonary carilage there was a harsh, rasping, rubbing,
crumbling sound, and associated with this a loud, blowing mur-

mur unaaccompanied by a thrill.

At the aortic carilage a systolic murmur was heard, which
was transmitted to the right sternio-clavicular articulation, but
could not be detected in the right carotid. From these physi-
cal signs it was evident that there was left ventricular hyper-
trophy with moderate dilatation, associated with mitral regur-
gitation. As the jugular veins pulsated slightly, and the mitral
murmur was transmitted so far to the right, it is probable that
there was also tricuspid regurgitation. The murmur at the base
of the heart was probably faint. There was a slight enlarge-
ment of the area of dullness of the liver and spleen, but they
could not be felt below the edge of the ribs. There was slight
congestion of the kidneys, but the other organs were normal.
The legs and thighs were moderately oedematous, and the sero-
tum, which had been decidedly enlarged, was then no larger
than a moderate-sized pear.

The third case occurred in a man aged twenty-seven years,
moved, a native of Zanzíbar, South Africa. His wife and fam-
ily were healthy. He lived in Bombay for three months prior
to going on board ship. He was admitted to the Lazaretto on
November 11th, and at that time Dr. Boenning found him in the
following condition:

He had had difficulty in walking since the middle of Septem-
ber, was weak and enfeebled, and had had chills and fever.
His legs were slightly edematous, and there was a distinct dia-
tonic murmur, soft in character, and best heard over the ensiform
carligale. His spleen was considerably and the liver moderate-
ly enlarged. His urine contained a trace of albumin. There
was much abdominal tenderness, nausea, and some vomiting.
On the morning of November 13th he had a pronounced chill,
which was repeated on November 15th. At the appearance of the first chill the free administration of quinine was begun, the effect of which, however, did not become plainly manifested until November 15th or 16th. This man exhibited in his blood the hematozoon of malaria, and also profound changes in the corporeal elements. His nerve disturbances have been marked. He presented areas of anesthesia over the extremities, abdomen, and pectoral regions, interspersed with areas of hyperesthesia. Nor did these remain constant, for the areas of insensibility became, after the lapse of twenty-four to thirty-six hours, hyperesthetic. Repeated tests with the galvanic current showed the reaction of degeneration in the affected muscles.

On admission his temperature was 101°½ F.; then descended to 98° F. the next morning; then rose to 104° F., descending the following morning to 97°½ F., where it remained from the 13th to the 15th, when again there was a rise to 104° F. On the 16th it descended to 102° F., and rose in the evening to 102°½ F., descending the following morning to 99° F., after which time it remained normal.

An examination of the blood on November 27th showed it to be normal in color, consistence, and coagulability. Microscopically the red blood-cells were normal in size and shape, with the exception of a few microcytes and an occasional megacyte. To the naked eye the red blood-cells appeared normal in color, though Fleischl's hemometer showed but sixty per cent. of hemoglobin. The Thoma-Zeiss hemocytometer gave 4,575,000 red corpuscles to the cubic millimetre, or ninety-one per cent., so that each red blood-cell contained two thirds its normal quantity of hemoglobin. The white corpuscles were normal in size, number, and appearance. At this date the area of normal sensation extended along the right thigh in the lower third, especially in the popliteal region, and for a distance of five inches below the joint. The remaining portions of the skin were absolutely anesthetic and analgetic, and the penetration of the needle was carried to the point of drawing blood without producing pain.

Sensibility of the mucous membrane of the mouth and hands was preserved. The knee-jerk was exaggerated, and the pupillary reflexes were normal. The thoracic and abdominal viscera were examined with negative results, with the exception of the heart, which gave the physical signs of enfeeblement.

Remarks.—These men were all sailors, and shipped on board the steamship Lanark at Bombay, where they had been living for three months. The crew was made up of Egyptians, Turks, Indians, Lascars, Bombayans, South Africans, Soudanes, etc. The ship was in good sanitary condition, and the voyage lasted eighty-two days, during which time they lived principally upon salt fish, of poor quality and insufficient in quantity, and occasionally partook of small quantities of rice. Each of these three men had the appearance of our negroes, both in color and in the formation of the mouth, although none had their characteristic thick lips. Their hair was short and twisted, the skin was greasy, and the perspiration possessed that peculiar disagreeable odor so commonly observed among the black race. While in the hospital they refused to eat pork, but ate freely of every thing else that was placed before them.

The greatest interest in these cases surrounds the question of etiology. Beri-beri has been observed in Japan, in portions of Africa, and in the East and West Indies, and, as has been shown by Scheube and Bialy, it is an endemic peripheral multiple neuritis. Muir believed it to be due to fish, more especially decomposed fish, while others attribute it to rice, and certain it is that these cases would tend to bear out Muir's theory. It is true that these men existed for eighty-two days upon a diet that seldom falls to the lot of man, consisting as it did almost exclusively of fish and rice. The fish was of a peculiar variety, and was brought on board and prepared by the Hindus. Some of it was dried, and much of it was spoiled. Further, the men stated that the quantity of food allotted to each was totally insufficient, more particularly when its quality was considered. All of the crew considered themselves very much superior in every way to the Egyptians, and for that reason they (the Egyptians) were only given to eat that which others refused. Then, too, the Egyptians would eat food killed and cooked by any one, whereas the remainder of the crew would only eat that which was killed and cooked by one of their own nationality. The Egyptians really were the most civilized of all, two of them speaking English fairly well, and while the whole crew were on shore at the Lazaretto the Egyptians sat at a table and used knives, forks, spoons, etc., while the others ate with their hands, sitting in circles upon the ground. Each Egyptian ate about six meals a day while on shore at the Lazaretto, and when they first landed they were half famished and excessively weak, so much so that they could scarcely stand or walk. After remaining in the hospital a few days, where they received plenty of good food and were well cared for, three of the eight were able to return to the ship before it sailed, on November 29th; one died suddenly, one eloped, and the remaining three, which are the subjects of this paper, improved so that they were able to return home on December 4th. There were several deaths during the voyage, but it is not known whether or not they were in Egyptians. It is interesting to note that the other members of the crew were practically free from disease, only one complaining of a slight swelling of the lower extremities. There was no scurvy.

The main facts, as here briefly narrated, seem to point conclusively to poisoning by some substance in the decomposed fish, probably of the nature of muscarine. In support of this view it may be stated—

1. That only the Egyptians were affected.
2. That they alone partook of the decomposed fish.
3. That the other men did not manifest this disease, even though exposed to the same general conditions, because their diet was more generous in quantity, more varied, and of better quality; and
4. That the blood examination, both microscopically and bacteriologically, showed no parasites.

These curious incidents partake of the nature of an experiment on a large scale, and the escape of the other men proves conclusively that the cause of this disease was not a general one—i.e., that it was not due to carbonic-acid gas generated in the cargo of sugar, as has been supposed by Dr. A. S. Ashmead; nor due to a specific poison or germ, as believed by Musso and Moulo, of Montevideo, and Simmons, of Yokohama; nor to rice, as believed by Takuki, of Tokio, but to a chemical poison or toxine like muscarine.

Cases of multiple neuritis due to this cause have been reported by Dr. J. J. Putnam, occurring among the New England fishermen who frequent the Great Banks.

Serious Symptoms Produced by the Bite of a Spider.—In the Nouveau Montpellier médical for February 9th H. Guibert relates the histories of two cases of serious poisoning following the bite of a spider. Cases of this kind, he says, being relatively rare, and, further, the noxious action of the sting of this insect having been stuntedly disputed, even denied, he thought it would be useful to give an account of these cases.

In the first case, observed by the author himself, the patient, a man forty years old, was stung on the right knee. The pain persisted for some time, but was not very marked, so that the patient was able to go on with his work for about half an hour, when suddenly he felt a very sharp pain near the injured part
and radiating toward the lumbar region of the same side. He became depressed, and a cold perspiration broke out, followed by trembling. The author saw him an hour after the symptoms appeared. He was then suffering from very sharp pains in the lumbar region and in the nape of the neck, the calves of the legs were attacked with true cramps, and the pulse was very small and frequent—from 92 to 100. The face was drawn and covered with a cold perspiration; it expressed great pain and considerable fear. He complained of a sensation of cold which bottles of hot water and thick coverings could not dispel. The axillary temperature was 98.3° F. The author found on the knee two small brownish points, by no means painful, surrounded by a redness due to friction with ammonia, which had been prescribed by an apothecary who had been called in before the author saw the patient. The ganglia of the groin were not swollen. M. Guibert cauterized the involved region and prescribed the immediate administration of a stimulating potion of ammonium acetate and alcohol, to be taken alternately with very strong coffee; at the same time he employed at once frictions with alcohol over the entire body. During the day the patient's condition scarcely changed; although he became a little warmer, the cramps persisted, also the pains in the lumbar region and in the neck. The following night he was restless, there was slight delirium, and he talked a great deal. The next day a slight amelioration was observed, the cramps had almost entirely disappeared, only the abdomen was very painful to the touch. The patient urinated easily, and no albumin was found in the urine. The cardiac pulsations were more energetic and less frequent, and the patient was quieter. On the following day the amelioration was marked; nothing remained but sharp colic and an irresistible desire to have the bowels moved, which it was impossible to satisfy. The author then prescribed six hundred and seventy-five grains of sodium sulphate, but this was rejected by repeated vomitings, which persisted during the day; they ceased, however, at night, when the patient was able to take a considerable quantity of champagne. A gentle purgative enema was then prescribed, which produced a breaking up, the stools showing a hemorrhagic appearance. Gradually, however, under the influence of rest and of diet, complete quiet returned and all the symptoms disappeared, and on the eighth day the patient got up completely cured.

In the second case, which was observed by M. Gombert, the patient was stung on the right ankle, and in a few seconds the pain became so violent that he could not walk, and had to be carried to M. Gombert's house. He presented very alarming symptoms of poisoning; there were extremely painful cramps and generalized convulsive tremblings, and the whole body was shaken with oscillations which became more and more frequent and had the appearance of tetanic contractions. These attacks lasted scarcely a minute, but returned at the end of four or five minutes. In the interval the patient said he suffered all over. However, he could drink, raise himself, and hold himself erect; his mental faculties were perfect, and the pulse was strong and regular. On the ankle two almost imperceptible points were found, which were not at all painful, even on pressure. Chloral and potassium bromide were administered, and diminished the number and the intensity of the convulsive attacks; the patient was then able to return to his home. A few hours later the cramps and the pains had ceased completely, but were replaced by diarrhœa and vomiting. The vomited matter was mixed with blood; blood was found also in the stools, and later on in the urine. Some hours afterward there were bloody diarrhœa and hematuria, but the general condition was quite good. On the third day the patient was much better, and on the fourth day all danger had disappeared.
